

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

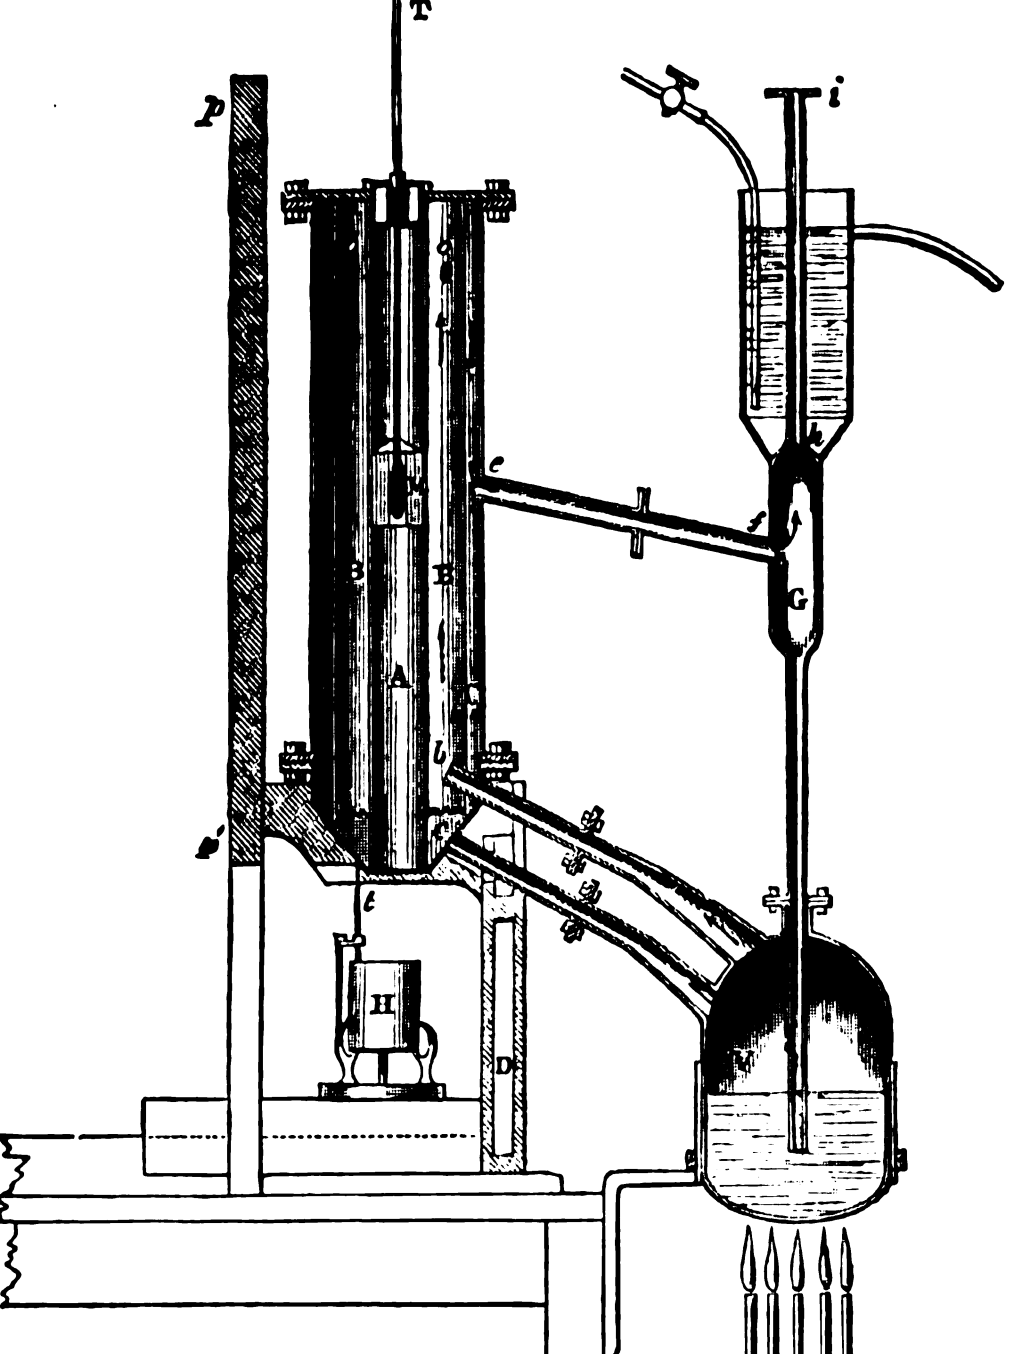
Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.



+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

LIST OF CONTRIBUTORS.

EDMUND ATKINSON, Ph.D. F.C.S.
Professor of Chemistry at the Royal Military College, Sandhurst.

FRANCIS T. CONINGTON, M.A. F.C.S. (the late)
Fellow of Corpus Christi College, Oxford, and Examiner in Natural Science at that University; Author of a 'Handbook of Chemical Analysis.'

WILLIAM DITTMAR, Esq.
Principal Assistant in the Chemical Laboratory of the University of Edinburgh.

FREDERICK FIELD, F.R.S. F.R.S.E.
(lately) Professor of Chemistry at St. Mary's Hospital.

GEORGE C. FOSTER, B.A. F.C.S.
Professor of Physics at University College, London.

MICHAEL FOSTER, M.D.
Professor of Physiology at Trinity College, Cambridge.

EDWARD FRANKLAND, Ph.D. F.R.S.
Professor of Chemistry at the Royal School of Mines.

FREDERICK GUTHRIE, Ph.D. F.C.S.
Professor of Physics at the Royal School of Mines.

M. L'ABBÉ A. HAMY,
Paris.

MICHAEL HANHART, Esq.
Lithographer.

A. W. HOFMANN, LL.D. F.R.S. V.P.C.S.
Professor of Chemistry at the University of Berlin.

WILLIAM S. JEVONS, M.A.
Cobden Professor of Political Economy at Owens College, Manchester; (lately) Gold Assayer in the Sydney Royal Mint.

CHARLES E. LONG, Esq. F.C.S. (the late)
Analytical Chemist.

WILLIAM ODLING, M.B. F.R.S.
Professor of Chemistry at the Royal Institution of Great Britain, Author of a 'Manual of Chemistry.'

BENJAMIN H. PAUL, Ph.D. F.C.S.
Consulting Chemist.

THOMAS RICHARDSON, Ph.D. F.R.S. &c. (the late)
Reader in Chemistry at the University of Durham.

HENRY E. ROSCOE, Ph.D. F.R.S. F.C.S.
Professor of Chemistry at Owens College, Manchester.

WILLIAM J. RUSSELL, Ph.D. F.C.S.
Professor of Chemistry at St. Bartholomew's Hospital.

J. A. WANKLYN, F.R.S.E. F.C.S.
(lately) Professor of Chemistry at the London Institution.

C. GREVILLE WILLIAMS, F.R.S.
Author of a 'Handbook of Chemical Manipulation.'

ARTHUR WINCKLER WILLS, Esq.
Analytical and Manufacturing Chemist, Wolverhampton.

DICTIONARY OF CHEMISTRY.

H.

HÆMAPHEIN. *Blood-brown.* (Simon, *Medicin. Chem.* i. 328; Handw. d. Chem. 2te. Aufl. ii. [2] 157.) A brown substance, probably a product of the decomposition of hæmatin, obtained from blood by the following process:—Dried blood is repeatedly exhausted with boiling water, warm ether, and lastly with alcohol containing sulphuric acid, and the latter solution, after supersaturation with ammonia, is evaporated to dryness. The residue is exhausted with alcoholic ammonia, the solution is again evaporated to dryness, and the residue is exhausted with ether, and then repeatedly with water, in which the hæmaphein dissolves. To free it from still admixed hæmatin, it is dried, dissolved in boiling alcohol, separated again by evaporation, then dissolved in cold alcohol, and the alcohol is evaporated. The product thus obtained is a brown mass difficult to pulverise, soluble with brown-red colour in cold alcohol, less soluble in water and in ether. It does not melt when heated, but burns with a bright flame, without leaving any ash. The solution in dilute alcohol forms brown precipitates with lead, copper, mercurous and silver salts. Sanson obtained a body of similar colour to the above by treating blood successively with alcohol and water.

HÆMATEIN. $C^{16}H^{12}O^4$, or $C^{16}H^{10}O^3$. (Erdmann, Ann. Ch. Pharm. xliv. 294.—Hesse, *ibid.* cix. 232.)—A substance produced from hæmatoxylin by abstraction of 2 at. hydrogen, a change which takes place by the action of oxygen under the influence of alkalis. The best mode of preparing it is to sprinkle about 20 grms. of hæmatoxylin in a basin with sufficient ammonia to dissolve it, stirring continually, and warming the liquid gently as long as the hæmatoxylin remains in excess. It must now be exposed to the air, and ammonia added from time to time by small quantities, so that the liquid may always smell of it, care being however taken not to add too much ammonia, as it would cause decomposition. The liquid after a little while assumes a dark red colour, appearing almost black when viewed in a stratum of moderate depth. It then contains hæmateate of ammonium, and on being slightly supersaturated with acetic acid, deposits hæmatein in the form of a bulky brown-red mass, like ferric hydrate, which by drying acquires a deep green colour and metallic lustre: its powder in thin layers, exhibits a red colour.

Hæmatein dissolves slowly in cold, more readily in boiling water. On quickly evaporating a solution prepared at the boiling heat, it becomes covered with shining green scales, which sink to the bottom and are gradually replaced by others. Sometimes also the solution solidifies in a gelatinous mass, which yields micaceous laminæ when suspended in water. Hæmatein likewise dissolves in alcohol and very sparingly in ether. It dissolves with red-brown colour in the mineral acids, less easily in acetic acid. Sulphydric acid decolorises it, but does not convert it into hæmatoxylin. It is carbonised by heat.

Hæmatein unites readily with bases. *Potash* dissolves it, forming a blue solution, which turns brown on exposure to the air. *Ammonia* dissolves it with a fine purple colour, which likewise turns brown in the air.

Digitized by Google

The last-mentioned solution contains hæmateate of ammonium, which is likewise formed when a solution of hæmatoxylin in ammonia is exposed to the air. The salt deposited by gradual evaporation is a dark violet, granular powder, which, when examined by the microscope, appears to be composed of transparent, violet, four-sided prisms. It contains, according to Erdmann's analysis, 56·26 per cent. C, 5·17 H, and 6·72 N (mean), whence Gerhardt (*Traité*, iv. 303) deduced the formula $C^{16}H^{16}(NH^4)^2O^6$ (57·5 C, 5·4 H, and 8·3 N). Hesse, by leaving the solution to stand for two or three days in a cool place, obtained crystals in which he found 51·87 C, 5·78 H, and 3·55 N (mean), agreeing nearly with the formula $C^{16}H^9(NH^4)O^5.4H^2O$, which requires 51·75 C, 5·66 H, and 3·77 N. Hæmateate of ammonium dissolves readily in water and alcohol. The alcoholic solution is red-brown, but becomes purple on addition of water. The salt gives off water and ammonia at 100° C. and must therefore be dried over sulphuric acid at ordinary temperatures; even then it sometimes decomposes. Over sulphuric acid in vacuo, it gives off all its ammonia and leaves hæmatein (Erdmann). According to Hesse, it gives off all its water and ammonia at 130° C., leaving hæmatein as a very hygroscopic powder, having a blackish violet colour with green iridescence.

Hæmatein thus obtained contains, according to Hesse's analysis, 67·66 per cent. carbon, and 3·50 hydrogen, agreeing nearly with the formula $C^{16}H^{10}O^5$, which requires 68·08 C and 3·54 H. Erdmann found in his hæmatein 62·66 per cent. C and 4·16 H (mean), whence he deduced the formula $C^{16}H^{20}O^{14}$. Gerhardt (*Traité*, iv. 302) proposed the formula $C^{16}H^{12}O^6$, which, however, does not agree very well with Erdmann's analyses, requiring 64·0 per cent. C and 4·0 H. Hesse suggests that Erdmann's hæmatein may be a dibasic acid, $\left.\begin{matrix}C^{16}H^{10}O^4\\H^2\end{matrix}\right\}O^2$, and the product, $C^{16}H^{10}O^5$, obtained by himself, the corresponding anhydride; on this supposition, the two ammonium-salts above mentioned are, perhaps, $\left.\begin{matrix}C^{16}H^{10}O^4\\(NH^4)^2\end{matrix}\right\}O^2$ and $\left.\begin{matrix}C^{16}H^{10}O^4\\H.NH^4\end{matrix}\right\}O^2.3H^2O$.

The solution of hæmateate of ammonium forms coloured precipitates with many metallic salts: with acetate of *lead* it produces a deep blue precipitate; with sulphate of *copper*, violet-blue; with *protochloride of tin*, violet; with *iron-alum*, black. With chloride of *barium* it forms a dark purple liquid, which becomes brown on exposure to the air. It reduces nitrate of *silver*, but has no action on mercuric chloride. According to Hesse, it forms with *chloride of barium*, *chloride of calcium*, and especially with *chloride of sodium*, precipitates of various colours; no precipitate with hyposulphite of sodium; with *acid sulphite of ammonium*, a gelatinous precipitate, which disappears on boiling.

HÆMATIN or **HÆMATOSIN.** The red colouring matter of the blood-corpuscles. (See Blood, i. 607.) Lehmann (Compt. rend. xl. 385) first showed that it may be obtained in the crystalline state. R. Schwarz (Zeitschr. f. die ges. Naturwissench. xi. 225) prepares it in this state by submitting the comminuted clot of ox-blood, freed as much as possible from serum, to pressure, and agitating the expressed liquid by small portions with a saturated solution of oxalic acid, with addition of alcohol and a large quantity of ether. The clear dark brown solution, decanted after a few minutes and left to stand for some weeks over chloride of calcium, deposits the hæmatin in small black nodules made up of cubes, which may be freed from admixed oxalate of calcium by means of dilute hydrochloric acid. Less distinct crystals may be obtained by leaving the ethereal solution to evaporate freely; but the quantity is always small. A solution of hæmatin obtained as above from horse-blood, yielded, on standing, small rush-shaped or spindle-shaped crystals, red-brown by transmitted light. Hæmatin may be obtained in the amorphous state by distilling off about a third of the ether from the solution, and mixing the residue with a large quantity of water. The black flocks thus precipitated are washed with water by decantation; then boiled with strong acetic acid, to free them from albuminous compounds, as long as the liquid is rendered turbid by ferrocyanide of potassium; and, lastly, the precipitate is boiled with water, alcohol, and ether in succession, and then again treated with water. The crystallised compound may be subjected to the same treatment without undergoing any alteration. Hæmatin thus prepared is tasteless and inodorous, insoluble in water, cold alcohol, and ether; partially (?) soluble in hot alcohol, easily in acidulated alcohol, whence it is precipitated by water. The solution in acidulated alcohol is decolorised by peroxide of lead. Hæmatin likewise dissolves easily in slightly alkaline liquids, but not in strong sulphuric or hydrochloric acid. Silver, lead, and copper-salts form precipitates in the ammoniacal solution. Hæmatin, when burnt, leaves a residue of ferric oxide mixed with small quantities of calcic phosphate.

The following analyses of hæmatin by Schwarz, give results not differing greatly from those formerly obtained by Mulder (whence the latter deduced the formula $C^{32}H^{32}FeN^4O^8$), but agreeing better with the formula $C^{68}H^{32}FeN^4O^8$.

When an alcoholic solution of crystallised hæmatin is boiled with nitric acid, the whole of the nitrogen of the hæmatin is removed, and a non-azotised acid is formed, together with a substance which reduces cupric oxide in alkaline solution, and ferments with yeast, yielding alcohol and carbonic acid.

The name *hæmatin* is sometimes also used as a synonyme of HÆMATOXYLIN.

HÆMATINONE. A red glass known to the ancients, and used for mosaics, ornamental vases, &c.; it is mentioned by Pliny, and occurs pretty frequently among the ruins of Pompeii. Its colour is a fine red, intermediate between red lead and vermilion. It is opaque, harder than common glass, takes a fine polish, has a conchoïdal fracture, and a specific gravity of 3·5. The red colour, which is due to red oxide of copper, is completely destroyed by fusion, and cannot be restored by any addition whatever. The fused mass has a greenish black colour, which reducing agents merely convert into a muddy brown-red. Hæmatinone contains no tin, and no colouring substance except cuprous oxide.

This antique glass may be exactly imitated by the following process, discovered by Pettenkofer (Dingl. pol. J. cxlv. 122):—100 pts. of silica, 11 lime, 1 magnesia, 33 litharge, and 50 carbonate of soda, are fused together, and to the clear white glass thus produced are added 25 pts. of scale oxide of copper, somewhat later 2 pts. of scale oxide of iron, and, lastly, a small quantity of charcoal. On leaving the fused mass to cool slowly, a liver-coloured glass is obtained, which, when further heated (for 6 to 12 hours) till it softens, is converted into hæmatinone of a splendid red colour, in consequence of the separation of a red cuprous compound within its mass.

A more fusible glass, made by melting together 100 pts. silica, 10 lime, 0·5 magnesia, 40 litharge, 60 carbonate of soda, 30 scale oxide of copper, 2 alumina, and 3 scale oxide of iron, exhibits, after once slow cooling in the air-furnace, a great number of red points, diffused through a yellowish vitreous mass; on cutting and polishing this glass, the red points appear as beautiful tufts of needle-shaped crystals.

When part of the silica in hæmatinone is replaced by boric anhydride (by adding borax to the melted mass), a dark-coloured, dichroïtic, crystalline compound is obtained, called astralite (i. 429).

Pettenkofer is of opinion that the same crystalline cuprous compound (whether pure cuprous oxide, or more probably cuprous silicate) which imparts the red colour to hæmatinone, constitutes likewise the crystalline spangles contained in aventurin glass (i. 477), which in fact he has produced by fusing hæmatinone with a quantity of iron filings, sufficient to reduce about half the copper contained in it to the metallic state (the metal then settling down in the form of a regulus, and leaving a deep greenish black, scarcely transparent glass above), heating this glass for some time to the temperature at which it softens, and then leaving it to cool very slowly. (Jahresb. d. Chem. i. 1061; ix. 798.)

HÆMATITE. Native sesquioxide of iron. (See IRON, OXIDES OF.)

HÆMATO-CRYSTALLIN. A crystalline substance obtained from blood (i. 606). It has the composition of the albuminoïds, and if quite pure would probably be colourless, but it has never yet been obtained perfectly free from hæmatin.

HÆMATO-GLOBULIN. Syn. with HÆMATO-CRYSTALLIN.

HÆMATOÏDIN. A crystalline substance often found in extravasated blood (i. 607). It appears to be produced by the decomposition of hæmatin; but the nature of the transformation has not been exactly made out. According to Verdeil and Dollfus (Compt. rend. xxx. 306), crystals resembling hæmatoïdin may be obtained from ox-blood by filtering it after coagulation by heat; evaporating the solution to a syrup, and mixing it with alcohol; strongly concentrating the liquid filtered from the resulting precipitate; and mixing it, when cold, with dilute sulphuric acid. Fat globules then separate on the surface of the liquid, and sometimes red crystals resembling hæmatoïdin.

Digitized by Google

Robin (Compt. rend. xli. 506) found a considerable quantity of hæmatoïdin in an hepatic cyst, forming hard, brittle prisms of 118° and 62°, and of a bright, orange-red colour. According to Valentiner (Jahresb. f. Chem. 1859, p. 656), gall-stones, bile, and the livers of persons affected with jaundice, yield, when treated with chloroform, a crystalline substance differing from all previously known ingredients of bile, and agreeing in all respects with hæmatoïdin.

HÆMATOSIN. See HÆMATIN.

HÆMATOXYLIN, also called *Hematin.* $C^{16}H^{14}O^6$. (Chevreul, Ann. Chim. lxxx. 128.—Golfier-Besseyre, Ann. Ch. Phys. [2] lxx. 272.—Erdmann, Ann. Ch. Pharm. xliv. 292.—Leblanc, *Traité de Chimie* de Dumas, viii. 102.—O. Hesse, J. pr. Chem. lxxv. 218; Ann. Ch. Pharm. cix. 332.)—A crystalline substance contained in logwood (*Hæmatoxylon Campechianum*), and the source of the colouring properties of that well-known dye. In the pure state, however, it has little or no colour, but is converted into a colouring matter under the influence of alkalis and oxygen.

It is prepared by leaving the commercial extract of logwood—previously mixed with quartz-sand to prevent agglomeration—in contact with 5 or 6 times its volume of ether (not anhydrous) for several days, agitating from time to time; then decanting the brownish-yellow solution; distilling off the ether; mixing the syrupy residue with water; and leaving it to itself in a loosely covered vessel. If no water were added, the liquid would simply dry up to a gummy mass; but, if a sufficient quantity of water is present, the hæmatoxylin crystallises in the course of a few days. The crystals are washed with water and freed from adhering mother-liquor by pressure between filtering paper. The mother-liquor mixed with the wash-water yields another crop of crystals by spontaneous evaporation. A kilogramme of logwood treated several times with ether yields from 100 to 120 grms. of hæmatoxylin. (Erdmann.)

Hæmatoxylin thus prepared has more or less of a yellow colour, but by recrystallisation from water containing a little sulphite of ammonium, it may be obtained in colourless crystals. (Hesse.)

Hæmatoxylin forms two kinds of crystals containing respectively 3 and 1 at. water. The trihydrated crystals, $C^{16}H^{14}O^6.3H^2O$, obtained as above, belong to the dimetric system. Ordinary combination $\infty P\infty$. P, with $P\infty$ subordinate. Length of principal axis = 0·63 (nearly). Angle of the terminal edges of the primitive octohedron, P = 124°. The crystals are transparent, generally very brilliant, and sometimes of considerable length. They give off their water (15·1 per cent.) in vacuo at ordinary temperatures.

The *monohydrate*, $C^{16}H^{14}O^6.H^2O$ (containing 5·6 water), is obtained by leaving a solution supersaturated at mean temperature to stand for some time, in crystals of considerable size, with smooth and sometimes curved faces, and consisting, according to a preliminary determination by Naumann, of hemihedral trimetric combinations, $oP . \frac{P}{2} . m\breve{P}\infty$. The same hydrate is obtained in granular crystals, by pouring a solution of hæmatoxylin, supersaturated at the boiling heat, into a cold vessel containing a small quantity of solution of acid sulphite of ammonium. (Hesse.)

Dehydrated hæmatoxylin contains, according to Erdmann's analyses, 63·17—63·66 per cent. carbon, and 4·65—4·70 hydrogen, whence Erdmann deduced the formula $C^{16}H^{12}O^{5}$. Gerhardt, however (*Traité*, iv. 299), suggested the more probable formula, $C^{16}H^{14}O^6$, which requires 63·5 per cent. C, 4·5 H, and 31·9 O.

Hæmatoxylin dissolves slowly and sparingly in cold *water*, easily in *alcohol* and *ether* (Erdmann). It dissolves in a saturated solution of *borax* more easily than in pure water, forming a neutral or slightly acid liquid, which exhibits a bluish fluorescence, and from which the borax is not precipitated by alcohol. This solution, mixed with hydrochloric, acetic, or sulphuric acid, solidifies to a dense mass, in which granular crystals of monohydrated hæmatoxylin quickly form; but on addition of solution of chloride of sodium, potassium, or ammonium, ferrocyanide of potassium, or acid sulphite of ammonium, it deposits hæmatoxylin as a white amorpheus mass. When acid sulphite of ammonium is added by drops to the same solution, hæmatoxylin is at first deposited in the form of an amorphous gummy precipitate, which re-dissolves on boiling the liquid, and reappears on cooling; but on continuing the addition of the acid sulphite to the syrupy liquid, a point is at length attained at which the amorphous hæmatoxylin disappears, and crystals of hæmatoxylin are soon afterwards obtained. When amorphous hæmatoxylin is dissolved in boiling water, and a drop of hydrochloric acid added to the solution, crystals of hæmatoxylin, generally the monohydrate, are soon deposited. Hesse.)

Hæmatoxylin dissolves abundantly in a warm solution of *hyposulphite of sodium*, forming a purple liquid, which deposits amorphous hæmatoxylin on cooling. It dis-

Digitized by Google

solves with some difficulty in solution of *chloride of sodium*, more easily in a saturated solution of *chloride of barium* (this solution at first depositing crystals of the trihydrate, which gradually give place to those of the monohydrate), very abundantly in solution of *ordinary phosphate of sodium*, forming a liquid which behaves like the solution of hæmatoxylin in borax above mentioned, excepting that it exhibits a basic reaction. (Hesse.)

Hæmatoxylin has a strongly saccharine taste, like that of liquorice, very persistent, and without astringence or bitterness. Its solutions turn the plane of polarisation to the right. It reduces cupric oxide in an alcoholic solution containing alkali.

An aqueous solution of hæmatoxylin is not altered by contact with pure air or oxygen gas; but if the slightest trace of *ammonia* is present in the air, the liquid acquires a yellowish red colour, arising from the formation of hæmateate of ammonium; probably thus:

$$C^{16}H^{14}O^6 + O + NH^3 = C^{16}H^9(NH^4)O^5 + 2H^2O.$$

Hæmatoxylin melts in its water of crystallisation when moderately *heated*, and is completely carbonised at higher temperatures. *Chlorine* converts it into an uncrystallisable mass. With *nitric acid* it forms oxalic acid. *Sulphuric* and *hydrochloric acids* have but little action upon it.

With *bases*, hæmatoxylin forms compounds which, on exposure to the air, are converted into hæmateates. *Baryta-water*, added to a solution of hæmatoxylin freed from air by boiling, forms a white precipitate which soon turns blue if the air has access to it. *Potash* imparts to the solution a violet colour, quickly changing to purple and brown. With acetate of *lead*, neutral or basic, the solution yields a white precipitate, which quickly turns blue; with *cupric* acetate or sulphate, a greenish grey precipitate, which soon becomes dark blue with a coppery lustre. *Dichloride of tin* forms a rose-coloured precipitate, which does not change colour. *Iron alum* forms, after a while, a slight blackish violet precipitate. *Common alum* colours the solution light red, but does not produce a precipitate. *Chloride of barium* first colours the liquid red, and then forms a red precipitate. The solution of hæmatoxylin quickly reduces nitrate of *silver* and chloride of *gold*.

HÆMIN. A crystallised, intensely red substance, which may be prepared from blood in various ways, but is difficult to obtain in the pure state, and has therefore not been analysed. The crystals are obtained immediately on mixing blood, either fresh or boiled, with strong acetic acid. No crystals are formed, however, when blood coagulated by boiling is first washed with water and then treated with acetic acid (Teichmann, Pfeufer and Henle's Zeitschr. f. rat. Medicin, iii. 357; viii. 141). According to Krauss (Jahresb. f. Chem. 1861, p. 792), human blood may be distinguished with certainty from that of the ox, sheep, pig, mouse, or poultry, by the characters of the hæmin-crystals obtained from it.

HAFREFJORDITE. Oligoclase from Hafrefjord, in Iceland.

HAIDINGERITE. A hydrated arsenate of calcium, $2Ca''HAsO^4.3H^2O$, supposed to be from Baden or Joachimsthal, associated with pharmacolite. Occurs in minute crystals belonging to the trimetric system, mostly congregated in botryoïdal forms and drusy crusts. Specific gravity 2·848. Hardness 1·5 to 2·5. Lustre vitreous. Colour white. Streak white. Transparent or translucent. Sectile; their laminæ slightly flexible. (Dana, ii. 413.)

Crystals having the form and composition of haidingerite may be produced artificially by digesting carbonate of calcium at ordinary temperatures with excess of aqueous arsenic acid. (Debray, Ann. Ch. Phys. [3] lxi. 419.)

HAIR. Hair consists of a cylindrical tube clothed with minute scales, having their points directed towards the free extremity. The tube is filled with an oil, which gives the colour to the hair; in white hair this oil is colourless.

In the normal state hair is insensible, strongly electric, and a bad conductor of heat. In contact with the air, it swells and absorbs moisture, but does not putrefy. Chlorine first bleaches and then converts it into a resinous matter resembling turpentine.

Hair is insoluble in water. Heated with water in a sealed tube, it is decomposed, with liberation of sulphydric acid. A similar decomposition takes place with aqueous potash. Nitric acid turns it yellow, forming oxalic acid, sulphuric acid, and a peculiar bitter substance. Hydrochloric and sulphuric acids dissolve it, forming rose-coloured solutions. Alkalis dissolve it. Many salts and metallic oxides, and likewise certain organic substances, change the colour of red or white hair to black. A solution of nitrate of silver in ether, or the same salt mixed with lard, oil, slaked lime, or pyrogallic acid is commonly used for blackening hair.

Hair, when heated, becomes hard, swells and emits an odour of burnt horn, and in the open air, takes fire, burns with a bright flame, and leaves a residue of charcoal. By dry distillation it yields oily and ammoniacal products.

Digitized by Google

According to Von Laer, human hair contains 49·8 per cent. carbon, 6·4 hydroge 17·1 nitrogen, 5·0 sulphur, and 26·7 oxygen. It leaves by calcination from 0·32 1·85 per cent. of ash, consisting of 0·17 to 0·93 soluble matter, 0·658 to 0·390 oxi of iron, and 0·000 to 0·528 earthy salts. (Pelouze et Frémy, *Traité*, vi. 244.)

HAIR-SALT. A term applied to native *sulphate of aluminium*, $Al^2(SO^4)^3.9H^2$ and to *iron-alum*, $Al'''Fe(SO^4)^2.12H^2O$, these salts sometimes occurring in delica fibrous masses. (See ALUM and SULPHATES.)

HALLITE. Basic sulphate of aluminium, $2(Al^2O^3.SO^3).3H^2O$. (Syn. wi WEBSTERITE.)

HALLOYSITE or **HALLOYTE.** A hydrated silicate of aluminium contai ing a larger proportion of water than ordinary clay, which it otherwise resembl After drying in the air at ordinary temperatures, it retains nearly $2H^2O$, but drying in the kiln, the proportion of water is reduced to nearly that of common clay, v $Al^2O^3.SiO^2 + H^2O$. It occurs in white, soft, smooth masses, with conchoïdal wa fracture, adhering to the tongue, opaque or translucent at the edges only. Wh immersed in water, it does not fall to pieces but becomes more translucent. It readily decomposed by sulphuric acid. The following are analyses:—

(Gm. iii. 417.)

HALOGEN. The electro-negative radicle of a haloïd-salt.

HALOÏD SALTS. Berzelius applied this term to salts consisting of a met united with an electro-negative radicle, viz. *chlorides*, *bromides*, *iodides*, *cyanides*, & designating by the term, AMPHID-SALTS, those which were supposed to result fro the union of two binary compounds containing a common element, viz. the oxyge salts, sulphur-salts, selenium-salts, and tellurium-salts. The distinction between the two classes of salts is no longer retained, but the term *haloïd* is still occasional applied to the chlorides, bromides, iodides, fluorides, and cyanides.

HALOTRICHINE. A silky iron-alum, from the Solfatara, near Naples. (S SULPHATES).

HALOTRICHITE. A name applied sometimes to native iron-alum, sometim to native hydrated sulphate of aluminium. (See SULPHATES.)

HAMATHIONIC ACID. An acid produced by the action of sulphuric ac on euxanthic acid. Its composition has not been exactly determined. The bariu salt contains 31·4 per cent. baryta; the lead-salt, 61·6 to 62·4 oxide of lead. (S EUXANTHIC ACID, ii. 610.)

HAMPSHIRITE. (See STRATITE.)

HARDNESS OF MINERALS. A harder body is distinguished from a soft either by attempting to scratch one with the other, or by trying each with a file. give a definite character to the results thus obtained, Mohs introduced a scale hardness, consisting of ten minerals, gradually increasing in hardness from 1 to 10, vi

1. *Talc:* common laminated, light-green variety.
2. *Gypsum:* a crystallised variety.
3. *Calc-spar;* transparent variety.
4. *Fluor-spar:* crystalline variety.
5. *Apatite:* transparent variety.

Digitized by Google

5·5 *Scapolite:* crystalline variety.
6. *Felspar:* (orthoclase); white cleavable variety.
7. *Quartz:* transparent.
8. *Topaz:* transparent.
9. *Sapphire:* cleavable varieties.
10. *Diamond.*

The hardness of any given mineral may be determined by attempting to scratch it with some of the above minerals, or by trying to scratch a smooth surface of the successive members of the scale with a sharp corner of the substance to be examined; thus, if it scratches fluor-spar and is scratched by apatite, the hardness is between 4 and 5.

Or again, the relative hardness of a mineral may be determined by abrading one of its edges with a file. If the file abrades the mineral under trial with the same ease as fluor-spar, and produces an equal depth of abrasion with the same force, the hardness is said to be 4. If the mineral is abraded more easily than fluor-spar, but less easily than apatite, the hardness may be 4·25 or 4·5. In making these comparative trials, care must be taken to apply the file to edges of equal obtuseness. That part also of the specimen should be selected which has not been altered by exposure, and has the highest degree of transparency and compactness of structure. The pressure for determination should be rather heavy, and the file should be passed three or four times over the specimen.

Certain varieties of some minerals give a low degree of hardness under the file, owing either to impurities or imperfect aggregations of particles, whilst they scratch a harder species, showing that the particles are hard, but loosely aggregated; this peculiarity is exhibited by certain varieties of chiastolite, spinel, and sapphire.

Many minerals—kyanite and mica, for example—present different degrees of hardness on dissimilar faces. This inequality, like difference of colour, lustre, &c., in the faces, is confined to those primary forms which are developed upon unlike axes. (Dana, i. 180.)

HARMALA, ALKALOÏDS OF. (Gerh. iv. 9.—Handw. d. Chem. iii. 769.)—The seeds of the *Peganum Harmala*, a plant growing abundantly on the steppes of Southern Russia, especially in the Crimea, contain two organic bases called harmaline and harmine, probably in the form of phosphates; they are found in the seed-coating, not in the kernel. To obtain these alkaloïds, the pulverised seeds are exhausted in a percolating apparatus with water acidulated with acetic or sulphuric acid; and the brownish yellow extract, which contains the bases in the form of acetates, together with earthy phosphates, colouring matter, &c., is mixed with a solution of common salt, whereupon the hydrochlorates of the alkaloïds, which are insoluble in that liquid, are precipitated together with colouring matter. Nitrate of sodium may also be used instead of the chloride, provided care be taken that the extract of the seeds does not contain free sulphuric acid, as the nitric acid which would then be liberated might decompose the alkaloïds. The precipitate is collected on a filter, and washed with brine until the whole of the mother-liquor is removed; then dissolved on the filter with cold water, which leaves part of the colouring matter undissolved. The solution, treated with animal charcoal, and then at a temperature of 50° to 60° C. with ammonia added by small portions, yields the alkaloïds in the pure state, nearly the whole of the harmine being thrown down before the harmaline begins to separate. As soon as the latter body makes its appearance,—which may be known by examining the precipitate from time to time with the microscope, harmine crystallising in needles, while harmaline forms leafy scales,—the solution must be filtered hot, and the harmaline precipitated from it by ammonia.

The seeds contain about 4 per cent. of alkaloïds, of which one-third consists of harmine, and two-thirds of harmaline.

HARMALA RED. The seeds of harmala contain also a red colouring matter, which may be extracted by digesting them with alcohol for 8—14 days. It is insoluble in water, easily soluble in ether, and dissolves in all proportions in absolute alcohol. It unites with acids, forming red salts, and dyes wool or silk mordanted with acetate or sulphate of alumina, from the lightest rose-colour to the deepest scarlet. The colours do not, however, appear to be very fast. (Gm. xvi. 119.)

HARMALINE. $C^{13}H^{14}N^2O$.—Discovered by Göbel in 1837 (Ann. Ch. Pharm. xxxviii. 363); afterwards more minutely examined by Fritzsche (*ibid.* lxiv. 360; lxviii. 351, 355; lxxii. 306; lxxxviii. 327). It is colourless when pure; if it has a yellowish or brownish tint, it may be purified by suspending it in water, adding acetic acid in sufficient quantity to dissolve it, filtering to separate colouring matter, then precipitating with chloride or nitrate of sodium, or hydrochloric acid, washing the precipitate on a filter with a dilute solution of the reagent employed, dissolving it in tepid

Digitized by Google

water, treating the solution with animal charcoal till it exhibits a light yellow c and precipitating by caustic potash.

Harmaline crystallised from alcohol forms octahedrons belonging to the trin system, modified by the faces $\infty\breve{P}\infty$, $\infty\dot{P}\infty$, and $\dot{P}\infty$. Ratio of the vertical t horizontal axes, 1 : 1·804 : 1·415. Angles of the terminal edges in P = 116° 34 131° 18′; of the lateral edges in the same = 83° 54′. It is sparingly soluble in and ether, moderately soluble in cold alcohol, and very freely in boiling alcoho has a faint bitter taste; and colours the saliva yellow.

Harmaline, when heated, melts, gives off white vapours and becomes carbo Heated in a tube, it yields a white mealy sublimate. Oxidising agents, under c circumstances, convert it into a red colouring matter, insoluble in water, solu alcohol. By some oxidising agents, however, harmaline is converted into harmi loss of 2 at. of hydrogen; this change takes place when the acid chromate of harm is heated to 120° C., or when harmaline is heated with hydrochloric acid and al to which a little nitric acid is added. When nitrate of harmaline is heated with holic hydrochloric acid, the harmaline is converted into harmine. Harmaline, with excess of *nitric acid*, yields, first, nitroharmaline, then, by longer boiling, n harmine: with boiling *nitromuriatic acid*, it forms chloronitroharmine.

The salts of harmaline are yellow, have a bitter taste, and are for the mos easily soluble and crystallisable.

The *acetate* is obtained by spontaneous evaporation of a solution of harmali acetic acid, in the form of a syrup which becomes crystalline after a while. A sol of the acetate, mixed with acid carbonate of potassium, yields *acid carbonate of h line*, in the form of a precipitate composed of fine needles. The neutral alkaline c nates either form no precipitate with the salts of harmaline, or merely throw dow base.

The *neutral chromate* is a sparingly soluble, yellow, crystalline salt, which m obtained by adding acetate of harmaline drop by drop to a solution of neutral chr of potassium, saturated in the cold, filtering from the precipitate of harmaline produced, and adding more acetate of harmaline to the filtrate. The *acid chro* $2C^{13}H^{14}N^2O.H^2O.2CrO^3$, is produced by adding acid chromate of potassium to a c solution of harmaline, and separates immediately in oily drops, which, after a w become crystalline. When heated to 120° C., it is rapidly decomposed, yielding a limate of *harmine* and leaving a dark-coloured residue containing chromium.

The *hydrochlorate*, $C^{13}H^{14}N^2O.HCl.2H^2O$, forms long prismatic needles conta 12·3 per cent. water of crystallisation. It is moderately soluble in water and in alc The *chloroplatinate*, $2(C^{13}H^{14}N^2O.HCl).PtCl^4$, is a yellow precipitate.

The *hydrocyanate* forms a peculiar alkali. The *hydroferrocyanate* is a bric crystalline powder; the *hydroferricyanate* forms long dark green prisms. The *su cyanate* forms silky needles, sparingly soluble in cold, more soluble in boiling wa

Nitrate of harmaline, obtained by precipitating the acetate with dilute nitric a nitrate of ammonium, forms needles sparingly soluble in pure water, and almost luble in water containing nitric acid.

Oxalates.—When aqueous oxalic acid is boiled with excess of harmaline, cryst the neutral salt separate on cooling; and oxalic acid, added to the solution of crystals, precipitates the acid oxalate of harmaline.

Sulphates.—By digesting dilute sulphuric acid with excess of harmaline, and e rating the filtrate, the neutral sulphate is obtained as a yellow resin, which, whe over oil of vitriol, changes to a radio-crystalline mass.

Sulphite.—The solution of harmaline in aqueous sulphuric acid dries up to a y resin, exhibiting no traces of crystallisation.

Sulphydrate.—By mixing concentrated solutions of sulphydrate of ammoniu acetate of harmaline, slender prisms are obtained which quickly decompose on exp to the air, after separation of the mother-liquor.

Hydrocyan-harmaline, $C^{14}H^{15}N^3O = C^{13}H^{14}N^2O.HCy$, is a base containin elements of harmaline and hydrocyanic acid. It is obtained by dissolving harm in dilute boiling hydrocyanic acid and filtering hot, being then deposited in cr on cooling; or by pouring a solution of cyanide of potassium into a solution of of harmaline, or caustic potash into a solution of a salt of harmaline previ mixed with hydrocyanic acid. From aqueous solutions it is deposited in amor flocks, which give off hydrocyanic acid when dried in the air; the decomposition however, be prevented by dissolving the powder, while yet moist, in hot alcohol. still contains harmaline, it may be purified by suspending it in water and a acetic acid, which readily dissolves the harmaline, but exerts little or no action o hydrocyan-harmaline.

This base, when pure, forms thin rhomboïdal tables, which, when dry, under alteration by exposure to the air, or in vacuo, or even at 100° C. At a higher

Digitized by Google

perature, or when boiled with water or alcohol, it is resolved into harmaline and hydrocyanic acid. Suspended in water and boiled with a large excess of nitric acid, it is decomposed, giving off red vapours, and yielding a purple solution which deposits non-crystalline grains of a fine red colour, changed to green by ammonia. Hydrocyan-harmaline, heated with hydrochloric acid and chloride of potassium, yields a resinous product.

The salts of hydrocyan-harmaline are even less stable than those of harmaline. The base does not appear to combine with all acids. The hydrochlorate, $C^{13}H^{11}N^3O.CyH.HCl$, is a crystalline powder composed of small octahedrons with a rhombic base and secondary faces, whereas hydrochlorate of harmaline, when examined by the microscope, appears like an aggregation of long yellow prisms. The *nitrate* and *sulphate* are also crystalline.

Nitroharmaline. $C^{13}H^{12}N^2O^2 = C^{13}H^{12}(NO^2)N^2O$. *Chrysoharmine.*—This body, which is derived from harmaline by the substitution of 1 at. nitryl, NO^2, for 1 at. hydrogen, may be prepared:—1. By suspending 1 pt. of harmaline in 6 or 8 pts. of alcohol of 80 per cent., adding 2 pts. of strong sulphuric acid, and, when the solution is complete, 2 pts. of moderately concentrated nitric acid; heating the mixture on the water-bath; and as soon as the reaction, which is very brisk, is over, cooling it quickly to prevent secondary decompositions. The liquid then deposits sulphate of nitroharmaline, which is to be washed with alcohol containing sulphuric acid, thon dissolved in warm water, and precipitated by dilute potash or ammonia. If the nitroharmaline thus precipitated contains harmine or undecomposed harmaline, it may be freed therefrom by means of sulphurous acid, which forms a sparingly soluble salt with nitroharmaline, but very soluble salts with the other two bases.—2. By a process exactly similar to that which will be hereafter described for the preparation of nitroharmine, excepting that the nitric acid used must be weaker, viz. of specific gravity 1·12 instead of 1·40.

Nitroharmaline, precipitated from its salts by an alkali, is an orange-coloured powder composed of microscopic prisms; larger crystals are deposited from the alcoholic solution. It is but sparingly soluble in cold water, to which, however, it imparts a yellow colour; boiling water dissolves it much more freely. It is more soluble in alcohol than harmine or harmaline; sparingly soluble in cold ether, more soluble in hot ether. It dissolves in oils, both fixed and volatile; also in hot rock-oil. It melts at 120° C.

Heated with ammoniacal salts it decomposes them, expelling the ammonia. Nitric acid converts it into nitroharmine.

The salts of nitroharmaline are yellow. The *hydrochlorate*, $C^{13}H^{12}(NO^2)N^2O.HCl$, crystallises in small prisms; its solution, mixed with tetrachloride of platinum, yields the *chloroplatinate*, $2(C^{13}H^{12}(NO^2)N^2O.HCl).PtCl^4$, as a yellow precipitate, which ultimately assumes the form of minute prisms.

The *nitrate* crystallises in yellow needles, rather sparingly soluble in water, especially if it contains a little nitric acid. A perfectly neutral solution of this salt, mixed with ammoniacal nitrate of silver, yields a yellowish red flocculent precipitate, consisting of *argento-nitroharmaline*, $C^{13}H^{12}Ag(NO^2)N^2O.H^2O$.

A compound of *nitroharmaline with nitrate of silver* is obtained in light yellow crystalline flakes on mixing an alcoholic solution of nitroharmaline with nitrate of silver.

The *neutral sulphate* is obtained as a crystalline precipitate on saturating a solution of the acetate with sulphate of ammonium. The *acid sulphate*, $C^{13}H^{12}(NO^2)N^2O.H^2SO^4$, is produced by dissolving the base in excess of sulphuric acid, mixed with alcohol, or by dissolving it in strong sulphuric acid, and pouring the solution, drop by drop, into cold water. It is a pale yellow crystalline powder, nearly insoluble in cold water.

The *sulphite* is very little soluble in cold water, especially if acidulated with sulphurous acid.

The *acetate* is soluble; the *oxalate* crystallisable. The *hydroferrocyanate* is a yellow crystalline precipitate. The *hydroferricyanate* separates in oily drops, which solidify, after a while, to a crystalline powder. The *sulphocyanate* forms sparingly soluble microscopic needles.

Hydrocyano-nitroharmaline, $C^{13}H^{12}(NO^2)N^2O.CyH$, is obtained by dissolving nitroharmaline in a hot alcoholic solution of hydrocyanic acid; also, by leaving a concentrated solution of acetate of nitroharmaline, mixed with hydrocyanic acid, to evaporate; or by adding ammonia to a salt of nitroharmaline containing hydrocyanic acid. It forms slender yellow needles, which give off the odour of ammonia when moist, but are permanent when dry. By boiling with water, it is resolved into nitroharmaline and hydrocyanic acid. Decomposed also by strong ammonia or potash. It dissolves in strong sulphuric acid, and the solution, poured into a small quantity of water, yields needles, apparently consisting of an insoluble sulphate.

HARMINE. $C^{13}H^{12}N^2O$. (Fritzsche, *loc. cit.*, p. 7.)—This alkali, which contains 2 at. H less than harmaline, may be obtained either directly from the seeds of *Peganum harmala*, in the manner already described, or as a product of the oxidation of harmaline. Acid chromate of harmaline, heated to 120° C., decomposes suddenly with evolution of heat, and produces harmine, part of which volatilises and condenses on the sides of the vessel. A better process is to heat harmaline with a mixture of equal parts of hydrochloric acid and alcohol, to which a little nitric acid is added. The conversion of the harmaline is complete soon after the liquid begins to boil, and on cooling, hydrochlorate of harmaline is abundantly deposited in slender needles. The solution of this salt, decomposed by ammonia, yields the base.

Harmine forms rhomboïdal prisms of 124° 18′, and 55° 42′, nearly insoluble in *water*, very sparingly soluble, at ordinary temperatures, in *alcohol* and in *ether*. It is a weaker base than harmaline; nevertheless it expels ammonia from its salts at the boiling heat.

The salts of harmine are colourless, and mostly crystalline; their solutions have a yellow tint when concentrated, bluish when dilute. Alkalis and alkaline carbonates decompose them, precipitating the base.

The *acid chromate*, $2C^{13}H^{12}N^2O.H^2O.2Cr^2O^6$, is always formed on mixing an acid solution of harmaline with a soluble chromate. It is decomposed by heat, yielding a peculiar base.

The *hydrochlorate*, $C^{13}H^{12}N^2O.HCl$, forms needles containing 12·38 per cent. water, which they give off at 100° C. From alcohol, the salt is deposited in the anhydrous state. The *chloroplatinate*, $2(C^{13}H^{12}N^2O.HCl).PtCl^4$, is a flocculent precipitate, becoming crystalline when heated. The *chloromercurate* is deposited as a curdy precipitate from cold solutions, and crystalline from hot solutions. The *hydrobromate* and *hydriodate* resemble the hydrochlorate.

The *hydroferrocyanate* and *hydroferricyanate* are obtained as yellow precipitates.

The *nitrate* forms yellow needles, sparingly soluble in cold water, still less in water acidulated with nitric acid.

The *neutral oxalate* is a crystalline precipitate. The *acid oxalate*, $C^{13}H^{12}N^2O.C^2H^2O^4.H^2O$ forms radiating needles, containing 5·67 per cent. water, which they give off at 100° C.

The *neutral sulphate*, $2C^{13}H^{12}N^2O.H^2SO^4.2H^2O$, obtained by dissolving an excess of harmine in dilute sulphuric acid and evaporating, forms concentrically grouped needles containing 6·57 per cent. of water. The *acid sulphate*, $C^{13}H^{12}N^2O.H^2SO^4$, obtained by adding excess of sulphuric acid to a solution of harmaline in boiling alcohol, forms crystals similar in form, but anhydrous.

The *sulphocyanate* is obtained by precipitation in yellow needles.

Substitution-derivatives of Harmine.

Dichlorharmine. $C^{13}H^{10}Cl^2N^2O$. (Fritzsche, Petersb. Acad. Bull. v. 12.)—Produced by the action of hypochlorous acid on harmine. To prepare it, a very dilute solution (containing 1½ to 2 per cent.) of hydrochlorate of harmine is heated to boiling; 10 to 15 per cent. of strong hydrochloric acid is then added to it, and afterwards, the solution being still kept boiling, chlorate of potassium is thrown in, by small quantities at a time, until the brownish red colour which the liquid assumes at first, is changed to pure yellow. The ebullition is maintained a little while longer, so as to destroy a coloured product; the solution is then allowed to cool; and the crystals of dichlorharmine which separate are washed with dilute hydrochloric acid, or with solution of chloride of sodium, and purified by crystallisation from alcohol, or re-solution in water and precipitation by hydrochloric or nitric acid. On redissolving the hydrochlorate of dichlorharmine in a large quantity of hot water, and boiling it for several hours with a great excess of soda-ley, crystals of dichlorharmine are deposited, which must be recrystallised from alcohol.

Dichlorharmine forms soft white needles, insoluble in cold, very slightly soluble in boiling water. It dissolves in *alcohol*, *ether*, *benzene*, and *sulphide of carbon*, much more easily when heated than in the cold.

Dichlorharmine forms a compound with *iodine*, corresponding to di-iodide of nitroharmine (p. 11), and containing 46·45 per cent. iodine.

With *acids* it forms crystallisable salts, which, like those of harmine, are very difficultly soluble in water containing acids or salts. The mono-acid (neutral) salts are decomposed to a certain extent, with separation of dichlorharmine, when a large quantity of water is poured upon them. Ammonia throws down dichlorharmine from their solutions, as an amorphous, colourless jelly; solution of soda acts in the same way, but in this case the precipitate becomes crystalline when long boiled with a great excess of soda solution. Dichlorharmine displaces a trace of ammonia from a boiling solution of sal-ammoniac; part of the dissolved dichlorharmine separates out on cooling, the rest only on addition of ammonia to the filtrate.

Digitized by Google

Hydrochlorate of Dichlorharmine is obtained by dissolving the base in water containing hydrochloric acid, and precipitating by excess of hydrochloric acid. It crystallises from water in needles, from alcohol in larger crystals; chloride of sodium separates it from its solution in the form of a jelly which turns to needle-shaped crystals. It contains 2 at. water, which it gives off at 100° C., but reabsorbs 1 at. if exposed to moist air. When heated much above 100°, it becomes yellow and loses hydrochloric acid; between 180° and 200° it melts to a brown-yellow liquid, which dissolves in water and contains a newly formed base.

The *nitrate* is precipitated as a jelly, which afterwards changes to crystalline needles, by addition of excess of nitric acid to a solution of dichlorharmine in water containing nitric acid. It is anhydrous and less soluble in water than the hydrochlorate. When melted it gives off acid vapours and yields a brown mass, from the solution of which in aqueous alkalis acids throw down brown flocks.

Nitrate of dichlorharmine precipitates from *oxide of argentammonium*, a pale greenish jelly, containing silver. When hydrochlorate of dichlorharmine is mixed with nitrate of silver, a jelly is precipitated, without formation of chloride of silver, but, on adding nitric acid to the jelly, chloride of silver is formed.

Nitroharmine. $C^{13}H^{11}(NO^2)N^2O$. *Nitroharmidine.* (Fritzsche, Petersb. Acad. Bull. xii. 33, 225; Ann. Ch. Pharm. lxviii. 328; xcii. 330.)—Produced by the action of nitric acid on harmaline or nitroharmaline. It does not appear to be formed by the action of nitric acid on harmine. To prepare it, 1 pt. of harmaline is dissolved in 2 pts. of water, and the requisite quantity of acetic acid, and to the solution 12 pts. of nitric acid of specific gravity 1·40 are added in a thin stream. A violent evolution of red vapours takes place; and if the liquid be kept in a state of ebullition till the action is over, then cooled quickly, and treated with excess of caustic alkali, nitroharmine is deposited in the form of a deep yellow precipitate, while a resinous matter, formed at the same time, remains in solution. The product is purified by converting it into a hydrochlorate, and decomposing that salt with ammonia. Nitroharmine forms yellow needles, tasteless, sparingly soluble in cold, more soluble in boiling water. From boiling alcohol it separates in deep yellow octahedrons, which soon change into needles. Ether dissolves it but sparingly. It dissolves in rock-oil and in coal-tar naphtha. Heated with a solution of sal-ammoniac, it slowly eliminates ammonia. It unites with iodine, but is decomposed by chlorine and bromine.

The salts of nitroharmine have a slightly bitter taste, and mostly crystallise in yellow needles. The *hydrochlorate*, $C^{13}H^{11}(NO^2)N^2O.HCl + 2H^2O$, obtained by adding hydrochloric acid in excess to a solution of the base in acetic acid, or in hot water acidulated with a few drops of hydrochloric acid, crystallises in slender needles, which may be purified by recrystallisation from boiling alcohol. The *chloroplatinate* is soluble and crystallises in needles.

The *neutral nitrate* is but sparingly soluble in water, still less in dilute nitric acid: hence nitric acid gradually precipitates nitroharmine from the solutions of its other salts. It crystallises in yellow needles, which, if left in the acid liquor, gradually change to granular and rhomboïdal crystals of a deeper yellow colour. There appears also to be a *basic nitrate*, somewhat more soluble in water.

The hydrocyanate does not appear to exist by itself, but a double compound of *hydrocyanate of nitroharmine and mercuric cyanide* is deposited in granular crystals when cyanide of mercury is added to a boiling solution of acetate of nitroharmine and the liquid left to cool.

The *hydroferrocyanate* and *hydroferricyanate* are obtained by precipitation, the former in brown microscopic prisms, the latter in yellow grains. The *sulphocyanate* forms nearly colourless needles, sparingly soluble in cold, more soluble in hot water.

Di-iodide of Nitroharmine, $C^{13}H^{11}(NO^2)N^2O.I^2$, separates in yellowish brown agglomerated microscopic needles, on mixing the boiling solutions of iodine and nitroharmine in alcohol or coal-tar naphtha. It is nearly insoluble at ordinary temperatures in water, alcohol, ether, and coal-tar naphtha; slightly soluble at higher temperatures. It may be heated to 100° C. without decomposition. It is resolved into iodine and nitroharmine by boiling with alcohol, and more quickly with dilute sulphuric acid. It appears to form a crystalline salt with hydrochloric acid. It dissolves also in acetic and hydrocyanic acids, and these solutions yield crystalline compounds.

Bromonitroharmine. $C^{13}H^{10}BrN^3O^3 = C^{13}H^{10}Br(NO^2)N^2O$. *Bromonitroharmidine.*—When bromine-water is added to a very dilute solution of a salt of nitroharmine, the smell of bromine disappears immediately, and on addition of ammonia, bromonitroharmine is precipitated and may be purified by recrystallisation from alcohol. It resembles chloronitroharmine, forms salts with acids, and unites with bromine and iodine.

The *dibromide*, $C^{13}H^{10}BrN^3O^3.Br^2$, is formed on adding bromine-water in moderate excess to a solution of bromonitroharmine in weak alcohol, and separates on cooling and stirring the liquid, in yellow microscopic needles.

Digitized by Google

CHLORONITROHARMINE. $C^{13}H^{10}ClN^3O^3 = C^{13}H^{10}Cl(NO^2)N^2O$. *Chloronitroharmidine.* (Fritzsche, Petersb. Acad. Bull. xii. 225; Ann. Ch. Pharm. xcii. 330).—Produced by the action of chlorine on nitroharmine, or of nitromuriatic acid on harmaline.

Preparation.—1. When chlorine-water is added to aqueous hydrochlorate or acetate of nitroharmine, or chlorine gas is passed into the solution till the smell of chlorine becomes permanent, chloronitroharmine separates in the form of a jelly. If the action of the chlorine be too long continued, a yellow resin is produced. The mixture is heated to boiling, and the resulting solution is precipitated by the cautious addition of ammonia, drop by drop, with constant stirring. A more or less crystalline product is thus obtained, whereas, from cold solutions, a jelly is precipitated, which is difficult to wash.—2. A solution of 1 pt. harmaline in 2 pts. water and the requisite quantity of acetic acid, is poured into 12 pts. of boiling nitric acid of specific gravity 1·40, and 2 pts. of fuming hydrochloric acid are added to the mixture; or the harmaline solution is poured into the boiling mixture of the two acids. The liquid becomes red-brown, froths up strongly, and evolves a volatile substance which attacks the eyes, but deposits nothing but resin on cooling. In order to separate the dissolved chloronitroharmine, a solution of sal-ammoniac, cooled by placing lumps of ice in it, is poured into the liquid; this is diluted with about an equal bulk of water; and caustic soda is then added, until it smells strongly of ammonia, whereby an abundant precipitate of impure chloronitroharmine is thrown down. The product is washed with dilute hydrochloric acid and heated with water; the solution freed by filtration from undissolved resin, and precipitated by gradual addition of ammonia; and the precipitate purified by crystallisation from hot alcohol. The crude chloronitroharmine may also be dissolved in boiling water, with addition of just the necessary quantity of nitric acid, and precipitated as nitrate from the cooled filtrate by addition of nitric acid in excess; this salt, after being washed, may be dissolved in hot water, and pure chloronitroharmine precipitated from the boiling filtered solution by means of caustic ammonia.

Chloronitroharmine forms a bright yellow, brittle mass, composed of very fine needles, which cannot be distinctly perceived, even under a magnifying power of 300. Ammonia precipitates it from cold solutions, as an almost transparent, deep yellow, very bulky jelly, which shrinks very much on drying. It is tasteless in the solid state, slightly bitter and rough in solution. It gives off 11·4 per cent. water at 100° C. (2 at. = 10·98 per cent.), and becomes orange-yellow. It dissolves but slightly in cold *water;* more abundantly in boiling water, forming a yellow solution; with moderate facility in boiling alcohol; slightly in ether; abundantly in boiling coal-tar naphtha, and in rock-oil.

Chloronitroharmine dried at 100° C. leaves a reddish-yellow residue when alcohol or coal-tar naphtha is poured upon it, but dissolves completely when boiled with dilute nitric acid.—*Solution of iodine* converts it into di-iodide of chloronitroharmine. When mixed with solution of iodide of potassium, and then with nitric acid, it deposits a deep blue precipitate.

Chloronitroharmine unites with acids, forming yellow salts. When boiled with solution of sal-ammoniac, it slowly displaces a trace of ammonia.

The *hydrochlorate*, obtained by adding hydrochloric acid in excess to a solution of the base in hot alcohol, forms fine capillary crystals moderately soluble in water. It is precipitated from its aqueous solution by a large excess of hydrochloric acid, as a yellow jelly; by chloride of sodium in white flocks. On mixing the hot alcoholic solutions of this salt and tetrachloride of platinum, *chloroplatinate of chloronitroharmine*, $2(C^{13}H^{10}ClN^3O^3.HCl)PtCl^4$, is deposited on cooling in fine yellow prisms.

The *nitrate* forms stellate groups of slender needles. A perfectly neutral solution of this salt mixed with ammonio-nitrate of silver, yields a precipitate consisting of a compound of chloronitroharmine with nitrate of silver.

Sulphates.—A solution of chloronitroharmine in warm alcohol containing sulphuric acid deposits the *neutral sulphate* on cooling, in spherical groups of capillary needles. From a hot aqueous solution the salt is deposited in light yellow gelatinous flocks. The *acid sulphate* separates slowly in needles from a hot concentrated alcoholic solution of the neutral salt mixed with excess of sulphuric acid.

Di-iodide of Chloronitroharmine, $C^{13}H^{10}ClN^3O^3.I^2$, separates in slender needles resembling di-iodide of nitroharmine, from a mixture of the hot solutions of iodine and chloronitroharmine in alcohol or in coal-tar naphtha. It is more soluble in alcohol than the di-iodide of nitroharmine, and dissolves easily in warm alcoholic hydrocyanic acid, separating in rounded granules on cooling.

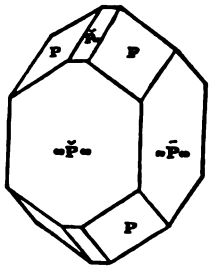
HARMOTOME. This term includes two isomorphous mineral species, identical in crystalline form, viz.: *Baryta-harmotome*, and *Lime-harmotome.*

Baryta-harmotome, also called *Cross-stone, Staurolite, Andreolite, Andreasbergolite, Morvenite.*—Crystals belonging to the trimetric system, being generally

Digitized by Google

rectangular prisms with four-sided summits set upon the lateral edges. Ordinary combination, P . $\infty\breve{P}\infty$. $\infty\bar{P}\infty$. $\bar{P}\infty$ (like *fig.* 528), often without $\bar{P}\infty$. Ratio of the axes: $a : b : c = 0{\cdot}9781 : 1 : 0{\cdot}684$. For P, the angle of the terminal edges in the brachydiagonal section = 121° 28′, in the macrodiagonal section, = 120° 1′; and the angle of the lateral edges (in a section parallel to the base) is 88° 44′. Cleavage most distinct parallel to $\infty\bar{P}\infty$. The crystals are generally twins, inserted crosswise into

Fig. 528.



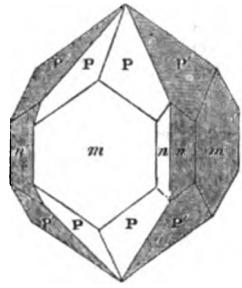


Fig. 529.

one another, as shown in *fig.* 529, in which the faces $\infty\breve{P}\infty$ are denoted by *n*, and $\infty\bar{P}\infty$ by *m*. For distinctness, the faces of one of the crystals are shaded (Kopp, *Krystallographie*, p. 263). Rarely massive. Specific gravity = 2·39 to 2·498. Hardness = 4·5. Lustre vitreous. Colour white, passing into grey, yellow, red, or brown. Streak white. Subtransparent to translucent. Fracture uneven, imperfectly conchoïdal. Brittle. Melts without intumescence before the blowpipe, forming a white globule. When finely pounded it is decomposed completely, though with difficulty, by hydrochloric acid.

The following are analyses of baryta-harmotome:—*a*, from Oberstein; *b*, from Strontian (Köhler, Pogg. Ann. xxxvii. 561); *c*, from Strontian (Connell, Ed. N. Phil. J., 1832, July, p. 33); *d*, *Morvenite*, from the same (Damour, Ann. Min. [4] ix. 339); *e*, from Andreasberg; *f*, from Strontian (Rammelsberg, *Mineralchemie*, p. 821).

	a.	*b.*	*c.*	*d.*	*e.*	*f.*
SiO^2	46·65	46·10	47·04	47·60	48·74	48·49
Al^2O^3	16·54	16·41	15·24	16·39	17·65	16·35
Fe^2O^3	. .	. .	0·24	0·65		
BaO	19·12	20·81	20·85	20·86	19·22	20·08
CaO	1·10	0·63	0·10			
K^2O }	1·10	0·90	1·72	1·55	. .	2·07
Na^2O }						
H^2O	15·25	15·11	14·92	14·16	14·66	13·00
	99·76	99·96	100·11	101·21	100·27	99·99

These analyses agree pretty nearly with the formula $BaO.Al^2O^3.5SiO^2 + 5H^2O$ (Rammelsberg), which requires 46·65 per cent. silica, 15·56 alumina, 23·79 baryta, and 14·00 water (the other constituents being regarded as adventitious), and by substituting $al = \frac{2}{3}$ Al. and regarding 2 at. hydrogen as basic, this formula becomes $(Ba''al^2H^2)Si^5O^{15}.4H^2O$, which is reducible to $\dot{M}^2SiO^3.\frac{2}{3}H^2O$, the formula of a metasilicate.

The composition of the mineral has, however, been hitherto generally represented by the formula $BaO.Al^2O^3.3SiO^3 + 5HO$, or $2(BaO.Al^2O^3).9SiO^2 + 10H^2O$; but this formula gives only 44 per cent. silica, which is considerably below that of all analyses which have been made of the mineral.

Baryta-harmotome occurs at Oberstein in Zweibrücken, in siliceous geodes; at Andreasberg in the Hartz; at Strontian in Argyleshire; in Norway on gneiss; and in simple crystals with analcime, in the amygdaloïd of Dumbartonshire. The variety called *Morvenite*, distinguished by the greater brilliancy of its crystals, is also found at Strontian. (Dana, ii. 323; Gm. iii. 446.)

Lime-harmotome or *Potash-harmotome*, *Phillipsite*, *Christianite*.—Isomorphous with the preceding, occurring also in twins. Specific gravity = 2·2 to 2·213. Hardness = 4 to 4·5. Lustre vitreous. Colour white, sometimes reddish. Streak uncoloured. Translucent—opaque. Before the blowpipe it intumesces slightly, gives off water, and melts to a translucent glass. Hydrochloric acid decomposes it easily, with separation of gelatinous silica.

The following are analyses of lime-harmotome:—*a*, from Annerode near Giessen

	98·64	101·08	99·48	100·22	100·21	

The composition of lime-harmotome has been represented by several different formu The quantities of calcium and potassium contained in it are somewhat variable, but composition appears to be, for the most part, that which is expressed by the form $\left.\begin{matrix}2CaO\\K^2O\end{matrix}\right\}.3Al^2O^3.12SiO^2+15H^2O$ (50·2 per cent. SiO^2, 21·3 Al^2O^3, 7·0 CaO, 6·5 K^2O, a 15·0 water), which, by substitution of *al* for $\frac{2}{3}$Al, as before, becomes $(Ca^2K^2al^6)Si^{12}O$ $15H^2O$, and is reducible to the general formula $M^{24}Si^{12}O^{36}.15H^2O$, or $M^2SiO^3.\frac{5}{6}H^2$ which is that of a metasilicate, and differs from the general formula of baryta-harm tome only in its amount of water.

Lime-harmotome occurs in the amygdaloïd of the Giant's Causeway, in large tra parent crystals. It is also found in Iceland; among the Vesuvian lavas; in sheaf-li aggregations at Capo di Bove, near Rome; and in long radiating crystals at Aci Caste in Sicily, and other localities. (Dana, ii. 324; Rammelsberg, *Mineralchemie*, p. 81

HARRINGTONITE. See NATROLITE.

HARRISITE. A variety of cuprous sulphide, Cu^2S, occurring in the Cant mine, Georgia, in crystals belonging to the regular system, and cleaving parallel to t faces of a cube (Shepard, Jahresb. f. Chem. 1857, p. 656). Genth (Sill. Am. J. [xxii. 449) regards it as a pseudomorph of copper-glance after galena.

HARTIN. $C^{16}H^{17}O$. *Psatyrin.*—A fossil resin resembling hartite. Massive, l crystallises from rock-oil in needles belonging to the trimetric system. White; des tute of taste and smell. Pulverises between the fingers. Melts at 210° C., and dist at 260°. Slightly soluble in ether. Gives, by analysis, 78·06 per cent. C, 10·92 and 11·02 O. It is found in the lignite of Oberhart, Austria. (Schrötter, Pogg. An liv. 45.)

HARTITE. C^3H^2.—Another fossil resin from the lignite of Oberhart. Obliq prisms belonging to the monoclinic system. Cleavage only in traces. Specific gravi 1·046. Hardness = 1. White, with a somewhat greasy lustre. Translucent. Britt Melts at 74° C., and distils at higher temperatures. Dissolves easily in ether, l readily in alcohol, and crystallises from each solution by evaporation (Haidinge Pogg. Ann. liv. 261). Gives, by analysis, 87·47 per cent. C and 12·05 H. (Schrötte

HATCHETTIN or *Mineral Tallow*, a fossil resin occurring in the coal measu of Glamorganshire; crystallised and amorphous in thin laminæ; like wax or sperm ceti in consistence. Specific gravity 0·916 at 15·5° C. White and transparent, wi nacreous lustre, but becomes black and opaque by long exposure. Greasy to the touc Melts at 46° C. Distils without change when cautiously heated. Dissolves sparing in boiling alcohol, and separates on cooling; sparingly also in cold ether, more eas in hot ether. Gives, by analysis, 85·9 per cent. carbon and 14·6 hydrogen (= 100·5 (Johnston, Phil. Mag. xii. 338.)

A similar substance is found at Rossitz, in Moravia. Specific gravity, 0·892. Har ness = 1. A variety from Loch Fyne, near Inverness, melts at 47° C. Another alli mineral from Merthyr Tydvil, melts at 76·6° C.

HAUERITE. Native disulphide of manganese, MnS^2, found at Kalinka, in Hu gary. (See MANGANESE, SULPHIDES OF.)

HAUSMANNITE. Native manganoso-manganic oxide, $MnO.Mn^2O^3$, or Mn^3O found at Ilmenau in Thuringia, at Ihlefeld in the Hartz, and one or two other local ties. (See MANGANESE, OXIDES OF.)

HAUYNE. A mineral consisting of silicate of aluminium, sodium, and calciu with sulphate of calcium, occurring in the lavas of Vesuvius, on Somma, and on t basalt of Niedermendig, near Andernach, on the Rhine. It crystallises in rhomb dodecahedrons, with cleavage parallel to the faces, sometimes distinct; commonly i

Digitized by Google

crystalline grains. Specific gravity 2·4 to 2·5. Hardness 5·5. Lustre varying from vitreous to greasy. Colour bright blue, occasionally asparagus-green. Streak bluish-white. Subtransparent to translucent. Fracture flat-conchoïdal to uneven. Before the blowpipe it decrepitates and fuses slowly to an opaque white or greenish-blue glass. Effervesces with borax, and forms a glass which is yellow when cold. The finely pulverised mineral dissolves completely in hydrochloric acid, the liquid depositing gelatinous silica when evaporated.

The composition of hauyne has been variously stated. From the analysis of the mineral from Mont Albano, Whitney (Pogg. Ann. lxx. 431) deduced the formula $3(Na^2O.Al^2O^3.2SiO^2) + 2(CaO.SO^3)$, or $3(Na_2^{al})SiO^4.CaSO^4$; from that of hauyne from Somma, Rammelsberg calculates the formula $2(Na^2O.Al^2O^3.2SiO^2) + (CaO.SO^3)$, or $4(Na_2^{al})SiO^4.CaSO^4$. The following table exhibits the numbers deduced from these formulæ, together with the results of the corresponding analyses:

Mont Albano.	(Whitney.) Calc.	Analysis.	*Somma.*	(Rammelsberg.) Calc.	Analysis.
$6SiO^2$ . .	32·20	32·48	$4SiO^2$ . .	34·29	34·06
$2SO^3$ . .	14·31	12·98	SO^3 . .	11·43	11·25
$3Al^2O^3$ . .	26·83	27·75	$2Al^2O^3$ . .	28·57	27·64
2CaO . .	10·02	9·96	CaO . .	8·00	10·60
$3Na^2O$ . .	16·64	14·24	$2Na^2O$ . .	17·71	11·79
K^2O . .	. .	2·40	K^2O . .	. .	4·96
	100·00	99·81		100·00	100·30

According to these formulæ, hauyne is allied to nosean, sodalite, and ittnerite, all of which are silicates of the form $M^2O.Al^2O^3.2SiO^2$, easily reducible to an orthosilicate, $(Ma_2^{al})SiO^4$ [$a' = \frac{1}{3}Al = 9·1$]. The formulæ of these minerals are in fact:

Hauyne: $\left.\begin{matrix}3\\ \text{or } 4\end{matrix}\right\} Ma_2^{al}SiO^4 . CaSO^4$

Sodalite: $3Ma_2^{al}SiO^4 . NaCl$

Nosean: $6Ma_2^{al}SiO^4 . Na^2SO^4$

Ittnerite: $6Ma_2^{al}SiO^4 . (CaSO^4; NaCl) + 6H^2O$

Hauyne from Niedermendig contains, according to Whitney, 33·90 SiO^2; 12·01 SO^3; 28·07 Al^2O^3; 7·50 CaO and 19·28 Na^2O = 100·73, and is composed of 1 molecule of nosean and 2 molecules of the Albano hauyne. The blue colour of hauyne appears to arise from a small quantity of a metallic sulphide similar to that which gives the colour to ultramarine. All specimens of hauyne, when treated with hydrochloric acid, give off at least a trace of sulphydric acid. (Dana, ii. 230; Handw. d. Chem. iii. 832.)

HAUYNOPHYR. A name applied to the lava of Melfi on the Vulturo. This lava is black or brown, and contains hauyne of various colours, and augite in slender needles. It is strongly attacked by acids. When it is treated with an equal weight of a mixture of 2 pts. hydrochloric acid and 1 pt. water, 30·2 per cent. remains undecomposed, consisting mainly of augite containing a large proportion of iron. The hauyne amounts to 22 per cent. (Rammelsberg, Jahresb. 1860, p. 807.)

HAYDENITE. Yellowish chabasite, from Jones's Falls, Maryland. (See CHABASITE.)

HAYESINE. (Syn. with BOROCALCITE.)

HAYTORITE. Pseudomorphous quartz, from the mine of magnetic iron at Hay Tor, in Devonshire. It has the form of datholite, and contains 98·5 per cent. silica and 0·2 ferric oxide.

HEAT. The word Heat is used in common language, both as the name of a particular kind of sensation, and to denote that condition of matter in which it is capable of producing this sensation in us. Any influence whereby external objects are rendered *hot*, or capable of exciting the sensation of heat, causes them at the same time to undergo other changes, which, being independent of the varying condition of our bodies, afford much more certain and more exact indications as to the condition of heat than is furnished by the sense of touch. Indeed, strictly speaking, our sensations bear no direct testimony with regard to the absolute degree of hotness of external objects, but rather to the fact of their imparting heat to our bodies, or removing heat from them. When these effects are produced in a moderate degree, we experience the sensations of heat and cold respectively; when the loss or gain of heat by our bodies is more rapid, it no longer produces any sensation to which a definite name can be assigned, but simply a feeling of pain; and the very rapid passage of heat either into or out of our bodies, causes a wound which is of the same kind in either case. The direct evidence of our senses with respect to the heat of external objects is therefore confined within comparatively narrow limits. Moreover, it is not always of the same

Digitized by Google

kind, even with respect to bodies in the same condition, as is easily proved by p one hand into hot water and the other into cold water, and after a short time i ing both and plunging them into lukewarm water, which will then feel cold to th which was previously in hot water, but warm to the other.

The most important of the other properties of the condition of matter consti heat, besides producing the sensation denoted by the same word, are the followi

1. Heat imparted to any body raises its *temperature*, that is, it not only caus body to produce the sensation of heat in a more marked degree, but its tende impart the property of so doing—in other words, its tendency to impart heat—to bodies is increased.

2. It modifies the relations between the density and elasticity of substanc general law being, that the hotter a body is, the less is its *elasticity of figure*, or ency to preserve a definite form and arrangement of parts, and the greater is its *ela of volume*, or tendency, if solid or liquid, to preserve a definite volume, and if g to expand indefinitely.

3. Heat causes solid bodies to become liquid, and liquid bodies to become ga The amount of heat required to produce these changes in any body varies wi special nature and with other circumstances, but they take place always and w exception, in the same order; that is, the solid state always corresponds to the l degree of heat, the gaseous state to the highest degree, and the liquid state intermediate degree.

4. Heat causes changes in the chemical composition of bodies, and also in electrical, magnetic, and optical properties.

The capacity of heat thus to effect changes characterises it as a form of en capable of being measured and expressed as a quantity, in terms of one or other c directly measurable effects which it produces. When thus expressed as a qua the condition of heat is found to be subject, like other forms of energy (mech energy, for example), to a law of conservation; that is, if in any system of b no heat is expended or produced through changes other than changes of temper then the total quantity of heat in the system cannot be changed by the mutual a of the bodies, but what one loses another gains; and if there are changes other changes of temperature, then if by those changes the total heat of the system is ch in amount, that change is compensated exactly by an opposite change in some other of energy. (See Rankine, *A Manual of the Steam Engine and other Prime M* ed. 1861, § 196, pp. 224, 225.)

Hence it follows that heat may be produced by the reversal of its effects: a instance, by the conversion of a liquid body into a solid, or of a gas into a liquid the compression of a gas, so as to make it occupy a smaller bulk; by the transmi through the point of junction of two dissimilar metals, of an electric current opp in direction to that which would be produced by the application of heat at the point; by the union of oxygen and hydrogen so as to form water, the effect of upon water being to resolve it into oxygen and hydrogen gases, &c. &c.

Similarly, heat may be caused to disappear—in other words, cold may be produc when a change, such as heat is capable of producing, is brought about by other me as when a solid is liquefied by solution, or when a liquid is vaporised; when a g expanded; when, through the point of junction of two dissimilar metals, an ele current is transmitted in the same direction as that which would be produced b application of heat at the same point, &c. &c.

The reversal of any of its effects does not, however, necessarily and under all cumstances, cause heat to be produced: instead of it an equivalent of some other for energy may be generated; thus, in Grove's gas-battery (Electricity, ii. 430) the pri result of the combination of oxygen and hydrogen gases is not the evolution of quantity of heat which would be required to decompose the water formed, but o equivalent amount of electrical energy. Neither is the disappearance of heat alw a necessary consequence of the production, by other means, of changes such as m be brought about by the action of heat itself: for example, in the decompositic water by the electric current, there is no disappearance of heat, but there is exper an amount of electrical energy, equivalent to the heat which would otherwise h been required to effect the same decomposition. Further, the most familiar and r practically important processes by which heat is produced, such as combustion, fric and percussion, are not such as can be directly reversed by the action of heat.

On the other hand, heat being a form of energy, every source or store of en may be considered as, directly or indirectly, a source of heat. The sources of h available to man may therefore be classified as follows:

1. The *Sun*. According to Pouillet, the total heating effect of the sun's rays f ing perpendicularly during 1 minute upon one square centimetre of the earth's surf including the portion absorbed by the atmosphere, amounts to 1·7633 times the qu

Digitized by Google

tity of heat required to raise the temperature of 1 grm. of water 1 degree centigrade, or to 1·7633 gramme-degrees. The mean heating effect on each square centimetre of the earth's surface, for every minute during 24 hours, is therefore = 0·4408 gramme-degree; or the total effect during one year is 232,000 gramme-degrees.* According to these data, the whole quantity of heat received by the earth from the sun in one year would be sufficient to melt a layer of ice over the whole surface of the earth of 32 metres (or 35 yards) in thickness. The whole of this supply of heat (which is less than the 2,300 millionth part of the total heat emitted by the sun) is not, however, directly available as such. According to Pouillet, nearly one-half is absorbed by the atmosphere, and of the heat so absorbed a considerable proportion goes to supply the mechanical energy of air in motion, or wind, and thus ceases, at least for a time, to exist as heat. Another portion is expended in causing the evaporation of water from the ocean and from the moist surface of the land: as will be shown in the sequel, a great part of this heat reappears when the evaporated water is returned to the earth as rain or otherwise; but the remainder is retained in a modified form in water which is deposited at a higher level than that from which it was evaporated, and so furnishes the mechanical energy, or water-power, of rivers and falling water. Still another portion of the total energy of the sun's rays is absorbed by growing plants, enabling them to convert carbonic acid and water into woody fibre: our ordinary modes of obtaining artificial heat—namely, by the combustion of wood and coal—are processes in which the heat thus absorbed is liberated by the reversal of the chemical changes which take place in plants while living. The warmth and mechanical force of animals are also derived, through the vegetable food which they consume, from the same source, whence are likewise derived, directly or indirectly, our chief supplies of electrical energy.

2. The *internal heat* of the earth. This we may consider as of two kinds: the actual heat, of which there is evidence in hot springs and volcanoes, as well as in the comparatively high temperature of deep mines; and the potential heat stored up in combustible minerals. By far the most important store of potential heat, namely, coal, represents, as we have already seen, a portion of the energy of the sun's rays which reached the earth during the growth of the plants from which it has been formed.

3. The *tidal wave*, caused by the earth's diurnal rotation, combined with the mutual motions of the earth, moon, and sun, is a source of heat which might be rendered practically available, by causing water-wheels, driven by the tidal waters, to generate heat by friction.

4. The *fall of meteoric stones* is a source of heat, practically insignificant, so far as the earth is concerned, but which has been supposed to play an important part in the maintenance of the heat of the sun.

(On the possible sources of energy available to man, see W. Thomson, Phil. Mag. [4] iv. 259.)

On the Measurement of Heat.

Before we can proceed further in the study of the properties and effects of heat, it is necessary that we should have some means of measuring and comparing different quantities of it. As already stated, quantities of heat may be expressed in terms of any of its directly measurable effects; but that one which is usually the most easily and accurately observable is alteration of temperature, and hence quantities of heat are commonly defined by stating the extent to which they are capable of altering the temperature of a known weight (such as 1 grm.) of a known substance (for instance, water). Accordingly, the unit of heat which will be employed in this article is the quantity, already spoken of as a gramme-degree, which is required to raise the temperature of 1 gramme of water from 0° to 1° centigrade. Heat is, however, capable of causing other alterations in the condition of bodies, such as the liquefaction of solid substances, without at the same time causing any alteration in their temperature; hence, another way in which a quantity of heat may be defined is by stating the amount of some known solid (ice, for example) which it is capable of liquefying, without causing any change in its temperature. Quantities of heat can also be expressed in terms of the mechanical or electrical energy to which they are equivalent; but as neither motion nor electricity can be generated by heat without the simultaneous expenditure of a greater or less quantity in causing a rise of

* The total quantity of heat received in a minute by a hemisphere of the earth's surface is the same as that which would fall on the great circle forming the projection of that hemisphere—that is to say, $1{\cdot}7633\ \pi R^2$ gramme-degrees (the radius being measured in centimetres). Hence, supposing the heat to be uniformly distributed over this surface, the quantity received in a minute by each square centimetre of surface is

$$\frac{1{\cdot}7633\ \pi R^2}{4\pi R^2} = 0{\cdot}4408 \text{ gramme-degrees;}$$

and as the earth performs its rotation in 24 hours and the year contains 365 days, it follows that the mean amount of heat received in a year by each square centimetre of the earth's surface is 0·4408 × 60 × 24 × 365, or in round numbers, 232,000 gramme degrees.

Digitized by Google

temperature in material substances, and since, therefore, the whole of a given q can never be transformed without loss into these other forms of energy, they serve for the direct measurement of heat. And in fact, whatever mode of measu is adopted, it is always necessary to take account of the temperature of the whose heat is to be estimated, and of those which are influenced by them, i that we may know the extent to which their temperature is altered; or on th hand, that we may convince ourselves that no such alteration takes place. Th surement of temperature, or *thermometry*, is therefore a necessary preliminary measurement of heat, or *calorimetry*.

Thermometry.—Temperature, or hotness, has already been defined as the te of one portion of matter to part with heat to other portions, and has been st depend on the quantity of heat which the portion of matter in question contain the purpose of defining different temperatures, it is obviously necessary to ad standard points, separated by a known and constant interval, which may ser measure by which to estimate the interval between any other two temperatures standard points usually adopted are the temperature of melting ice, and th perature of pure water boiling freely under a barometric pressure of 760 mill (= 29·92 inches) of mercury (measured at the melting point of ice). When tity of mercury is allowed to attain equilibrium of temperature with melting i afterwards with water boiling under the conditions above mentioned, it is fou its bulk in the latter case always exceeds its bulk in the former case by a certain c amount. The expansion of the mercury is here a measure of the quantity which the boiling water imparted to it after it had come to such a condition interchange of heat no longer took place between it and the melting ice; and s already observed, the mercury always expands by the same proportion of its bull temperature of melting ice, we may conclude that the quantity of heat which water can impart to a given mass of matter, exceeds that which melting ice can to the same mass, by a constant proportion; in other words, that the temper boiling water is higher than the temperature of melting ice, and that the interva separates them is always the same.

It is upon this principle that the use of the mercurial thermometer, and o instruments in which expansion is employed to indicate temperature, depends construction and use of this instrument in its various forms are fully described article THERMOMETER, to which the reader is referred. It will be sufficient state, that there are in frequent use three different modes of designating t standard points of temperature, and of subdividing the interval between them: the *centigrade* scale of Celsius employed in this Dictionary, in which the temp of melting ice is denoted by zero, and the temperature of boiling water b Réaumur's scale, in which the temperature of melting ice is likewise denc zero, but that of boiling water by 80; and Fahrenheit's scale, in which the temperature is marked 32, and the latter 212. The melting point of ice is th indicated by any of the following expressions:—

0° C., 0° R., and 32° F.;

and the boiling point of water by any of the following:—

100° C., 80° R., and 212° F.;

accordingly, 100 degrees centigrade are equivalent to 80 degrees Réaumur, and (= 212 − 32) degrees Fahrenheit, or 5 degrees C. = 4 degrees R. = 9 degrees F simplicity of these relations makes it easy, when a temperature is expressed ac to any of the three scales, to find an equivalent expression according to either other two. (See further the article THERMOMETER.)

Besides the mercurial thermometer, and the spirit thermometer, which is quite to it in principle and in the manner in which it is used, there are some other ments, which are advantageously employed in special cases, for the measuren temperature, and must therefore be briefly described here.

The *Weight-thermometer*.—This is a mercurial thermometer which differs fr common one, inasmuch as the expansion of the mercury consequent upon rise o perature is not read off directly from a divided scale, but is calculated from the of mercury which escapes from the instrument. It consists of a cylindrical glass voir, closed at one end, and terminated at the other by a short capillary glas which is so bent that, when the thermometer is placed in the position in which be used, its open end points vertically downwards. The mode of using it is as fo The thermometer is weighed while empty, and the reservoir and tube are ther pletely filled with pure mercury, the whole of the air being carefully expelled by b and allowing the instrument to cool while the open end of the capillary tube dips the surface of mercury, as in the usual process of filling a barometer or thermo

Digitized by Google

By surrounding the thermometer with melting ice, the instrument itself, as well as the mercury contained in it, is brought to the temperature of 0° C.: when this temperature has been reached by every part of it, the vessel of mercury is removed from under the open end of the capillary tube, and is replaced by a small tared capsule. The ice is now removed, and the outside of the thermometer is carefully dried. As the mercury contained in it returns to the temperature of the air (supposed above 0° C.), it expands, and, consequently, some of it escapes by the capillary tube into the tared capsule. The thermometer, and the capsule containing the mercury which has escaped from it, are now placed together in the balance and weighed; by deducting from the gross weight so obtained the weight of the instrument when empty, and that of the capsule, we obtain the weight W, of the quantity of mercury which fills the thermometer at 0° C.

The instrument is next heated to 100° C., by immersing it in the steam of boiling water, the same precautions being taken as in fixing the boiling point of the ordinary graduated thermometer (see THERMOMETER), and the mercury which escapes is collected in the tared capsule and weighed. Let w be the weight of the whole quantity of mercury which escapes from the thermometer when it is heated from 0° C. to 100° C.; then the coefficient of apparent expansion (see below, *Expansion of Liquids*) of the mercury contained in the thermometer will be

$$\delta = \frac{w}{(W - w)100} \quad . \quad . \quad . \quad . \quad . \quad . \quad (a)$$

Similarly, if w_t be the weight of mercury which escapes from the thermometer when it is heated to any other temperature, $t°$, which it is required to determine, we have

$$\delta = \frac{w_t}{(W - w_t)t}; \quad . \quad . \quad . \quad . \quad . \quad . \quad (b)$$

hence we get

$$\frac{w_t}{(W - w_t)t} = \frac{w}{(W - w)100},$$

or—

$$t = \frac{w_t}{w} \cdot \frac{W - w}{W - w_t} \times 100$$

The value of δ, deducible from equation (a), was found by Dulong and Petit (who were the first to employ the weight-thermometer) to be equal to $\frac{1}{5.5.5.5}$, and by substituting this value in equation (b) the value of t is given independently of the preliminary experiment above described, in which the thermometer is heated to 100° C.; but some uncertainty is thus introduced into the determination, inasmuch as the value of δ varies to a slight extent with the kind of glass of which the thermometer is made.

The weight-thermometer is capable of giving very accurate results when employed to indicate the mean temperature of any considerable space, such as an oil- or water-bath, the temperature of which changes so slowly that it may be assumed, at any given instant, to be the same as that of the thermometer. The size of the instrument depends upon the purpose for which it is to be employed: it is well that it should be of such a length as to reach from one end to the other of the space whose temperature has to be measured, and its capacity ought to be such that the weight of mercury driven out by the smallest rise of temperature which it is required to estimate may be capable of being accurately determined by the balance. An obvious precaution in the use of this instrument is to keep the open end constantly under the surface of the mercury in the capsule, so that no air can enter in consequence of a diminution of temperature.

Regnault's *Air-thermometer* is an instrument which is applicable in the same kind of cases as the weight-thermometer, but has the advantage of giving accurate results at all temperatures below that at which glass softens, whereas the indications of the weight-thermometer are obviously confined to temperatures below the boiling-point of mercury. In construction, it closely resembles the latter instrument, and consists of a cylindrical glass reservoir about 2 centimetres (0·8 inch) in diameter and about 12 or 15 centimetres (4·8 or 6 inches) long, terminated at one end by a narrow glass tube of 1 or 2 millimetres internal diameter, which is bent at a right angle, at a short distance from the end farthest from the reservoir, and drawn out to a fine point. In this state, the instrument is placed in the space of which it is desired to know the temperature; and as soon as the instant arrives for which this temperature is required, the drawn-out point is sealed by fusion with the blowpipe, the height of the barometer and its attached thermometer (i. 512) being observed at the same time. The thermometer thus closed is then supported in a vertical position, the narrow tube downwards, and with the bent and sealed extremity of the latter under the surface of mercury; it is next opened by breaking off, under the mercury, as small a piece as possible of the point; and the reservoir is completely surrounded with melting ice. Owing to the contraction of the air in the thermometer as it cools, the mercury rises in the tube and

Digitized by Google

partially fills the reservoir; and, when the temperature of the thermometer and its contents has been reduced to 0° C., the height of the surface of the mercury in the reservoir, above that of the mercury outside the instrument, is measured by a cathetometer, the height of the barometer being carefully noted at the same time. The open end of the tube is now closed, while still under mercury, by pressing against it a pellet of soft wax; the ice is removed from the reservoir; and the instrument is taken out of the support, inverted, and weighed together with the mercury contained in it. The thermometer is next completely filled with mercury at 0° C. and weighed again, and lastly the weight of the instrument itself when empty is determined.

Let W be the weight of mercury which completely fills the thermometer, and let w be the difference between this weight and that of the mercury contained in it at the first weighing. These two weights then bear to each other the same proportion as the total capacity of the thermometer at 0° C. bears to the volume occupied—at 0° C. and under the atmospheric pressure diminished by the column of mercury read off by the cathetometer—by the air which the thermometer contained at the moment when it was sealed with the blowpipe. They may therefore be taken to represent respectively these volumes: we shall then have

$$W(1 + \kappa t) = w\frac{h}{H}(1 + \alpha t),$$

or—

$$t = \frac{W - w\frac{h}{H}}{w\frac{h}{H}\alpha - W\kappa};$$

where t is the temperature required;

H, the atmospheric pressure at the moment of sealing the thermometer with the blowpipe;

h, the pressure supported by the air in the thermometer at the moment of closing it with the pellet of wax = the barometric pressure observed at the same moment —the column of mercury read off with the cathetometer;

α, the coefficient of expansion of air for 1° C = 0·00366;

κ, the coefficient of cubical expansion of the glass of which the thermometer is made = 0·0000305, between 0° and 300° C., for common glass, and = 0·0000233 for crystal-glass from Choisy-le-Roi. (Regnault.)

(For the derivation of the above formula, see the section Expansion of Gases in this article; for further details of the air-thermometer, see Regnault, *Cours élémentaire de Chimie*, éd. 1854, iv. 64.)

Deville and Troost's *Iodine-pyrometer*.—For the measurement of temperatures above that at which glass softens, Deville and Troost employ a method which depends on essentially the same principles as the use of the air-thermometer, although the mode of experimenting differs considerably. Their apparatus consists of a globular flask of Bayeux porcelain of 280 or 300 c. c. capacity, with a neck 11 centimetres long and 4 mm. in internal diameter. A quantity of iodine is put into the flask, and the neck is nearly closed by a small plug of porcelain which lies loosely in the opening. When the flask is now exposed to a high temperature, the iodine is vaporised and the greater part escapes by the neck, driving out at the same time nearly the whole of the air. After the flask has been exposed for about twenty minutes to the temperature that is to be measured, the flame of an oxy-hydrogen blowpipe is allowed to play for an instant upon the porcelain plug lying in the neck: the plug is thus melted and closes the flask hermetically. When cold, the flask is cleaned and carefully weighed; the end of the neck is broken under boiled water or mercury, and the flask is weighed, together with the water or mercury which enters; it is then completely filled with water or mercury and weighed again; lastly, the flask is weighed when empty. From the weights thus obtained it is easy to calculate the capacity of the flask, and the volume of air which the iodine-vapour has failed to expel: the first weighing gives directly the excess of the weight of the flask and iodine-vapour over that of the empty flask. The observations which require to be made in each experiment are the following:—

Temperature of the balance	= $t°$
Atmospheric pressure	= h mm.
Excess of weight of flask after being heated and sealed full of iodine-vapour over weight of flask filled with air previous to the experiment	= i grm.
Capacity of flask	= v c. c.
Residual air	= a c. c.

Digitized by Google

Besides these data, the following constants are required in order to calculate the temperature at which the flask was sealed:—

Weight of 1 c. c. air at 0° and 760 mm. pressure . .	= 0·001293 grm.
Density of iodine-vapour referred to air as unity . . .	= 8·716
Coefficient of expansion of air for 1° C.	0·00366
Coefficient of cubical expansion of Bayeux porcelain for 1° C.	= 0·0000108

The required temperature, T, can now be calculated as follows:

let $I_v \left(= \frac{(v-a)\cdot 001293}{1 + \cdot 00366t} \cdot \frac{h}{760} + i \right)$ be the total weight of iodine-vapour contained in the flask at the moment of sealing, then

$$\frac{I_v}{0{\cdot}001293 \times 8{\cdot}716} \cdot \frac{(1 + 0{\cdot}00366\ T)\ 760}{h} = I_v$$

will be the volume of this vapour at the same moment; but

$$I_v + \frac{a\,(1 + 0{\cdot}00366\ T)}{1 + 0{\cdot}00366t} \cdot \frac{760}{h} = v(1 + 0{\cdot}0000108\ T)$$

and from this equation, in which T is the only unknown quantity, its value is easily found.

It is obvious that this method is applicable only for the measurement of maximum temperatures which can be maintained stationary for some time; but in cases where these conditions can be fulfilled, as in determining the boiling points of difficulty volatile substances (*e.g.* sulphur, cadmium, zinc) it is capable of yielding very accurate results.

A porcelain globe filled with air may be employed as a thermometer in the same way: the advantage of using iodine is that given differences of temperature correspond to greater differences of weight.

(See further Deville and Troost, Ann. Ch. Phys. [3] lviii. 267, 275, 285, 293.)

Mercury-pyrometer.—This instrument, proposed by Regnault (Ann. Ch. Phys. [3] lxiii. 40), is composed of a bottle made of cast or wrought iron, platinum or porcelain, having a capacity of 500 to 1000 c. c., and provided with a perforated lid which lies flat upon the neck of the bottle, the under surface of the lid (which has a considerably greater diameter than the neck) and the upper surface of the neck being ground together, so that by sliding the lid a little to one side, the bottle can be almost completely closed without removing it from the furnace, or other space whose temperature is to be determined. Before beginning the experiment, 10 or 15 grms. of pure mercury are put into the bottle, and it is then placed in the furnace, the lid being laid on so that the hole through it forms a continuation of the orifice of the neck; when the bottle has been in the furnace long enough to have thoroughly assumed the temperature of the latter, it is closed by drawing the lid sideways, then removed from the furnace, and quickly cooled. The mercury remaining in the bottle is poured out (it can be completely detached from the bottle by shaking a little water round in it), and weighed, either in the metallic state, or, when necessary, after solution in an acid and precipitation. When the following data are known, namely—

- v = capacity of the bottle in c. c. at 0° C.;
- κ = coefficient of cubic expansion of the substance of the bottle;
- h = atmospheric pressure at the moment of withdrawing the bottle from the furnace;
- d = density of mercury-vapour at temperatures at which it has the properties of a perfect gas;
- p = weight of mercury remaining in the bottle;

the required temperature, T, can be calculated.

The weight of mercury-vapour which fills the bottle at $T°$ is

$$= v \cdot \frac{1 + \kappa T}{1 + 0{\cdot}00366\ T} \cdot 0{\cdot}0012932 \cdot d \cdot \frac{h}{760} = p;$$

hence

$$\frac{1 + \kappa T}{1 + 0{\cdot}00366\ T} = \frac{760}{v \cdot 0{\cdot}0012932 \cdot d} \cdot \frac{p}{h} = M \cdot \frac{p}{h},$$

in which last expression M is a quantity which remains constant for the same bottle: we have therefore

$$T = \frac{1 - M\,\frac{p}{h}}{M \cdot 0{\cdot}00366\,\frac{p}{h} - \kappa}$$

Regnault's *Hydrogen-pyrometer* (Ann. Ch. Phys. [3] lxiii. 42) is an instrument whereby the temperature of a furnace or other heated space can be quickly determined at any required instant. It consists of a wrought iron tube one or two inches wide, and long enough to reach from one side of the furnace to the other, terminated at each end by a capillary tube of the same material, provided with a three-way cock. When the temperature of the furnace is to be determined, a current of pure and dry hydrogen is caused to enter the iron tube at one end, and allowed to issue freely into the air at the other; when the current of gas has been continued long enough to displace all the air, and to reduce any oxide that may have formed in the inside of the tube, it is stopped; the free end of the iron tube is connected with a copper tube filled with oxide of copper, and heated to redness by a row of gas-jets; the current of hydrogen is then replaced by a slow current of dry air, which sweeps forward the hydrogen into the copper tube, where it is completely converted into water. The water thus formed passes on to a weighed U-tube containing pumice-stone and sulphuric acid, and from its weight the temperature of the furnace can be calculated upon the same principle as when the mercury pyrometer is used. (For further details, and for figures of this apparatus and of that last described, see Regnault, *loc. cit.*)

The *Thermomultiplier*.—This instrument consists of a thermo-electric pile, connected with a delicate galvanometer; its construction, and the principles upon which its action depends, have already been explained in the article ELECTRICITY (ii. 413 and 443, 444). As a thermoscope, or instrument for rendering sensible heat of very low intensity, this apparatus is much more delicate than any other that has been devised, the heat given out by the human body producing a perceptible effect upon it, even at a distance of ten yards or more (Daguin, *Traité de Physique*, 2nd edit. ii. 34). As a differential thermometer, it is capable of giving accurate results, when the intervals of temperature to be measured are sufficiently small. But, since the direct indications of the instrument are not generally proportional to these intervals of temperature, it is necessary to construct, for each thermomultiplier, a table showing the interval of temperature to which each degree read off upon the instrument really corresponds. The following account of the method recommended by Melloni for constructing these tables is given by Tyndall (*Heat as a Mode of Motion*, p. 355), being translated by him from 'La Thermocrose,' p. 59:—

"Two small vessels are half-filled with mercury, and connected separately by two short wires, with the extremities of the galvanometer. The vessels and wires thus disposed make no change in the action of the instrument; the thermo-electric current being freely transmitted, as before, from the pile to the galvanometer. But if, by means of a wire, a communication be established between the two vessels, part of the current will pass through this wire and return to the pile. The quantity of electricity circulating in the galvanometer will be thus diminished, and with it the deflection of the needle.

"Suppose, then, that by this artifice we have reduced the galvanometric deviation to its fourth or fifth part; in other words, supposing that the needle being at 10 or 12 degrees, under the action of a constant source of heat, placed at a fixed distance from the pile, that it descends to 2 or 3 degrees when a portion of the current is diverted by the external wire; I say that by causing the source to act from various distances, and observing in each case the *total* deflection and the *reduced* deflection, we have all the data necessary to determine the ratio of the deflections of the needle, to the forces which produce these deflections.

"To render the exposition clearer, and to furnish, at the same time, an example of the mode of operation, I will take the numbers relating to the application of this method to one of my thermomultipliers.

"The external circuit being interrupted, and the source of heat being sufficiently distant from the pile to give a deflection not exceeding 5 degrees of the galvanometer, let the wire be placed so as to connect the two vessels of mercury; the needle falls to 1·5. The connection between the two vessels being again interrupted, let the source be brought near enough to obtain successively the deflections:—

$$5°,\ 10°,\ 15°,\ 20°,\ 25°,\ 30°,\ 35°,\ 40°,\ 45°.$$

Interposing after each the same wire, we obtain the following numbers:—

$$1{\cdot}5°,\ 3°,\ 4{\cdot}5°,\ 6{\cdot}3°,\ 8{\cdot}4°,\ 11{\cdot}2°,\ 15{\cdot}3°,\ 22{\cdot}4°,\ 29{\cdot}7°.$$

"Assuming the force necessary to cause the needle to describe each of the first degrees of the galvanometer to be equal to unity, we have the number 5 as the expression of the force corresponding to the first observation. The other forces are easily obtained by the proportion:—

$$1{\cdot}5 : 5 = a : x = \tfrac{5}{1{\cdot}5}\,a = 3{\cdot}333a,$$*

* That is to say, one reduced current is to the total current to which it corresponds, as any other reduced current is to its corresponding total current.

Digitized by Google

where a represents the deflection when the exterior circuit is closed. We thus obtain

5, 10, 15·2, 21, 28, 37·3

for the forces corresponding to the deflections,

5°, 10°, 15°, 20°, 25°, 30°.

"In this instrument, therefore, the forces are sensibly proportional to the arcs up to nearly 15 degrees. Beyond this the proportionality ceases, and the divergence augments as the arcs increase in size.

"The forces belonging to the intermediate degrees are obtained with great ease, either by calculation or by graphical construction, which latter is sufficiently accurate for these determinations.

"By these means we find,

Degrees . .	13°	14°	15°	16°	17°	18°	19°	20°	21°
Forces . .	13	14·1	15·2	16·3	17·4	18·6	19·8	21	22·3
Differences . .		1·1	1·1	1·1	1·1	1·2	1·2	1·2	1·3
Degrees . .	22°	23°	24°	25°	26°	27°	28°	29°	30°
Forces . .	23·5	24·9	26·4	28	29·7	31·5	33·4	35·3	37·3
Differences . .		1·4	1·5	1·6	1·7	1·8	1·9	1·9	2

"In this table we do not take into account any of the degrees preceding the 13th, because the force corresponding to each of them possesses the same value as the deflection.

"The forces corresponding to the first thirty degrees being known, nothing is easier than to determine the values of the forces corresponding to 35, 40, 45 degrees, and upwards.

"The reduced deflections of these three arcs are,

15·3° 22·4°, 29·7°.

"Let us consider them separately; commencing with the first. In the first place, then, 15 degrees according to our calculation, are equal to 15·2; we obtain the value of the decimal 0·3 by multiplying this fraction by the difference 1·1; for we have evidently the proportion

$$1 : 1{\cdot}1 = 0{\cdot}3 : x = 0{\cdot}3$$

The value of the reduced deflection corresponding to the 35th degree, will not, therefore, be 15·3°, but 15·2° + 0·3° = 15·5°. By similar considerations we find 23·5° + 0·6° = 24·1°, instead of 22·4°, and 36·7° instead of 29·7° for the reduced deflections of 40 and 45 degrees.

"It now only remains to calculate the forces belonging to these three deflections, 15·5° 24·1°, and 36·7°, by means of the expression $3{\cdot}333a$; this gives us,

the forces,	51·7,	80·3,	122·3.
for the degrees,	35,	40,	45.

"Comparing these numbers with those of the preceding table, we see that the sensitiveness of our galvanometer diminishes considerably when we use deflections greater than 30 degrees."

When one face of the thermopile is exposed to the action of heat, the needle of the galvanometer, with which the pile is connected, immediately leaves its position of equilibrium and swings considerably beyond the new position in which, after a series of gradually diminishing oscillations, it ultimately comes to rest, if the pile continues exposed to the same source of heat; and when the source of heat is removed, the face of the pile only gradually loses the increased temperature which it had acquired while exposed to its action, so that the return of the galvanometer needle to its first position is likewise gradual. These two circumstances would occasion a very considerable loss of time in making a numerous series of observations with the thermomultiplier, were it necessary each time to allow the needle to become stationary at the point of ultimate deflection; but Melloni observed that the arc through which the needle swings in its first oscillation is always the same for an ultimate deflection of the same amount, and hence, by constructing what he calls a *Table of Impulses*, or table giving the ultimate deflection corresponding to a first swing, or impulse, of any given amount, this loss of time may be avoided. With such a table, it is only necessary to observe the arc described by the needle in its first movement, and then to refer to the table for the ultimate deflection corresponding thereto.

Siemens's *Resistance Thermometer*.—In this instrument the actual indications of temperature are made by an ordinary mercurial thermometer: its peculiarity consists in the fact that it enables the temperatures of spaces to be determined into which a thermometer could not be introduced, or where, if introduced, it could not be observed. Its action depends on the increased resistance which a metallic wire offers to the passage of an electric current when its temperature is raised. (ELECTRICITY, ii. 467.)

Digitized by Google

Two perfectly similar coils of insulated wire are enclosed in two hermetically sealed copper cases. One is placed in the space of which the temperature is required, the other in a bath of water; and the temperature of the bath is altered until the electrical resistance of the two coils is exactly equal, an equality which can be readily tested by a differential galvanometer. The temperature of the bath will then clearly be equal to that of the space where the first resistance coil is placed. The connections are made with very thick copper wire, so that their resistance shall have little or no influence upon the result. The wires are coiled on an open copper cylinder of considerable diameter and length, so as to expose a large surface to the air or water in which they are placed. They in consequence take the temperature of the surrounding medium with great rapidity. (*Report on Electrical Instruments in the International Exhibition of* 1862, by Fleeming Jenkin.—Jurors' Reports, Class xiii. p. 93.)

This instrument is obviously adapted for determining the temperature of different depths of the sea, or of borings on land, and for other similar purposes. Its sensibility may be considerably increased by adopting a suggestion of Dr. Esselbach's, and constructing one of the coils, that one which is placed in the bath of water, of a material whose resistance increases more slowly with rise of temperature than that of the substance of which the other coil is made. The temperature of the bath would then have to be varied more than one degree, in order to compensate the alteration of resistance caused by a variation of one degree in the temperature of the medium surrounding the other coil.

Besides the instruments for measuring temperature which are described above and in the article THERMOMETER, already referred to, a great number of others, of various degrees of utility, have been suggested from time to time. But it is believed that the instruments here noticed are those most likely to be found practically useful by the experimental chemist. A large number of the older contrivances for thermometric purposes are very fully described in the treatise on *The Thermometer and Pyrometer*, published by the Society for the Diffusion of Useful Knowledge. (Library of Useful Knowledge, Natural Philosophy, vol. ii. 1832.)

Calorimetry.—The cases in which *quantities* of heat require to be measured are very numerous, and different methods and apparatus are required in nearly every case. In relation to every one of the effects of heat the question arises: How much heat is needed to produce this effect with a given intensity? hence calorimetric measurements have to be made in the study of each of these effects, while the nature of each will determine the manner in which such measurements can best be made. We shall, therefore, consider the different problems into which calorimetry enters, one by one as they occur, and shall now pass at once to the

QUANTITATIVE STUDY OF THE EFFECTS OF HEAT.

The following order will be adopted in this part of the subject:—

1. Changes of Temperature produced by Heat.
2. Changes of Volume produced by Heat.
3. Changes of State of Aggregation produced by Heat.
4. Relations of Heat to Chemical Affinity.
5. Relations of Heat to Electricity.
6. Relations of Heat to Mechanical Energy.

1. *Changes of Temperature produced by Heat.*—**Specific Heat.**—When equal weights of two different substances, say a pound of water and a pound of mercury are placed in two similar vessels, and exposed for the same length of time to the heat of the same lamp, or placed in front of the same fire, at equal distances from it, or otherwise treated so as to have an opportunity of taking up, each exactly as much heat as the other, it is found that, if of equal temperatures at the beginning of the experiment, they have no longer the same temperature at the end of it. The mercury is found to be much hotter than the water. Hence it is proved that a quantity of heat which is sufficient to raise the temperature of a given quantity of mercury through a given number of degrees, is only able to raise the temperature of the same quantity of water through a smaller number of degrees; in other words, more heat is required to raise the temperature of a given quantity of water one degree, than is required to raise the temperature of the same quantity of mercury one degree. Again, if we take two equal weights of water and mercury which have been heated to the same temperature say to 100° C., and place them under such conditions that, in cooling down to the temperature of the atmosphere, each shall give out exactly as much heat in each second as the other, it will be found that the mercury will have cooled down to the temperature of the atmosphere long before the water; hence, when its temperature is lowered by a given number of degrees, water gives out more heat than an equal quantity of mercury does in undergoing a similar alteration of temperature. Extending similar experiments to other substances, we should find that the quantity of heat needed to effect a given

Digitized by Google

change of temperature is different for almost every substance. These quantities of heat, expressed relatively to the quantity of heat required to raise the temperature of an equal weight of water from 0° to 1° C., are called the specific heats of the various substances. Thus, for instance, the statement that the specific heat of lead is 0·0314, implies that the quantity of heat which would suffice to raise the temperature of any given quantity of lead from 0° to 1° C., would raise the temperature of an equal quantity of water only from 0° to 0·0314°.

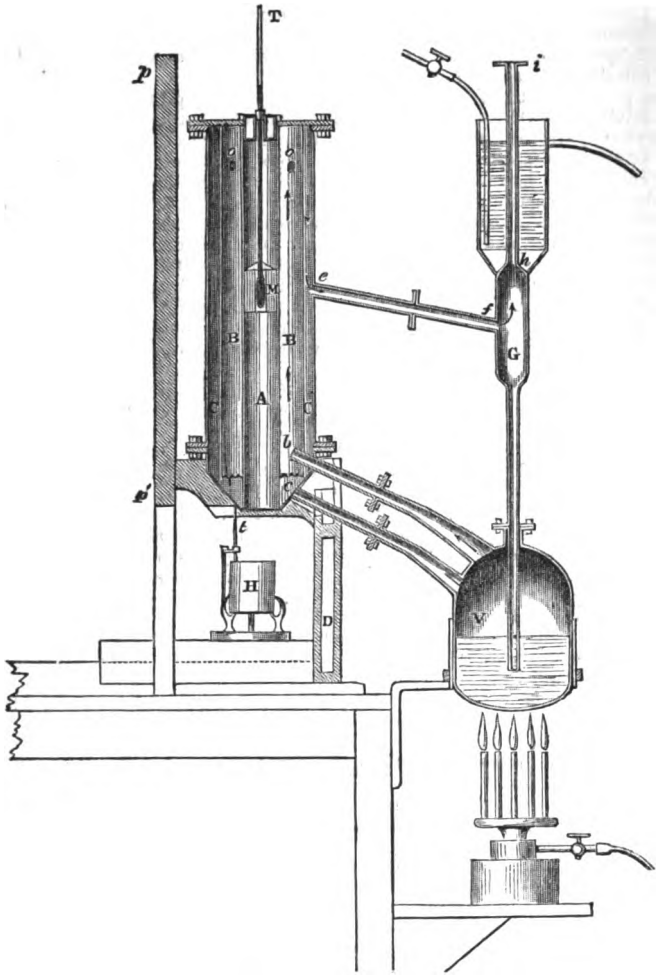
The power of heat, then, to cause changes of temperature depends upon the nature of the substance upon which it acts, just as we shall see in the sequel, that its power to cause changes of volume, or changes of any other kind, varies with the nature of the bodies submitted to its action.

Three principal methods have been employed for measuring the specific heats of different substances. Of these, much the most accurate is that known as the method of mixtures; we shall, therefore, describe it first. It consists in heating a known weight of the substance, whose specific heat is to be determined, to a known temperature, then plunging into a known weight of water, also at a known temperature, and determining the temperature of the mixture which results. In an experiment of this kind, let T be the temperature to which the substance was heated, t the initial temperature of the water, and θ the temperature of the mixture; and let the weight, in grammes, of the substance be W, and the weight of the water, w. Then it is plain that the heat which the substance has given out in cooling from $T°$ to $\theta°$ is the same as that required to heat the water from $t°$ to $\theta°$. Calling the hitherto unknown specific heat of the substance x, we shall have for the former quantity of heat, the expression $W(T-\theta)x$, and for the heat taken up by the water (whose specific heat = 1), $w(\theta - t)$. Hence

$$W(T-\theta)x = w(\theta - t);$$

or

$$x = \frac{w(\theta - t)}{W(T-\theta)}.$$



The most accurate determinations of specific heat that have hitherto been published are probably those made by Regnault (Ann. Ch. Phys. lxxiii. 5; *Ibid.* [3] i. 129; ix. 322; xxvi. 261 and 268; xxxviii. 129; xlvi. 257; lxiii. 5), by the method of mixtures. *Fig.* 530 (see p. 26), which is copied from his latest memoir on this subject, shows the disposition of apparatus usually employed by this investigator. The substance to be examined is contained in a basket of fine brass wire, M, suspended in the middle of an upright cylinder, A, of thin metal. This cylinder is surrounded by a larger concentric cylinder, B, and this again by a third cylinder, C. By the ebullition of water in the boiler, V, the annular space between A and B is kept constantly full of steam, which passes thence through the openings, *o o*, near the top of B, into the outer annular space comprised between B and C, and hence by the waste-pipe *ef* to the condenser G, and so back to the boiler. That portion of the steam which is liquefied in the cylinders B and C, returns to the boiler in the form of water by the pipe *c*. The temperature of the substance in M is shown by the thermometer T, the bulb of which occupies a cylindrical space left for the purpose in the middle of the basket of brass wire. The water into which the substance is to be plunged is contained in the calorimeter H, a small vessel of very thin and highly polished brass, supported upon three points, and carried by a foot which slides along a groove, so that, by a rapid and smooth motion, it can be brought directly under A, or removed to the farther side of the sliding screen, *pp'*, so as to be protected from the influence of heat given out by the heating apparatus C. When in its place under A, the calorimeter is protected from heat radiated by the boiler by the double screen D, between the two coatings of which a continual circulation of cold water is kept up. The temperature of the calorimeter is indicated by the thermometer *t*, the bulb of which is long enough to reach from just below the surface of the water to very near the bottom.

At the commencement of an experiment, the calorimeter is drawn back outside the screen *pp'*, and the basket containing the substance to be examined is suspended in the middle of the cylinder A by a silk thread, the cylinder itself being closed at top and bottom by hollow plugs to prevent loss of heat, one of which is shown in its place at the upper part of the figure. Steam from the boiler being allowed to circulate about A, the substance at M is gradually heated to nearly the temperature of boiling water. After, in general, about two hours, the thermometer T becomes stationary; but, for greater certainty that the temperature of the substance is uniform throughout, the heating is continued for at least another hour. The temperature of the water in the calorimeter is then observed by reading the thermometer *t* through a telescope, the temperature of the air being read off at the same time upon another thermometer. The calorimeter is quickly pushed under the heating apparatus; the plug at the bottom of the cylinder A is removed; and by loosening the cork which supports the thermometer T,

Digitized by Google

the silk thread from which the basket M hangs is liberated, and this with its contents allowed to fall into the water contained in H. The calorimeter is again drawn back behind the screen PP', and the basket is moved about in the water by an assistant, while the observer watches through the telescope the maximum temperature indicated

Fig. 530.

by the thermometer *t*. This maximum generally occurs one or two minutes after the immersion of the substance. Suppose that, in such an experiment, the following results were obtained:—

Weight of substance	M grm.
„ „ brass wire basket	p grm.
Temperature by thermometer T at moment of immersion . .	$T°$
Temperature by thermometer t at same moment	$t°$
Maximum temperature after immersion by thermometer t . .	$\theta°$
Weight of water in calorimeter, calorimeter and thermometer supposed included	A
Specific heat of brass	c

Digitized by Google

Then, calling the required specific heat of the substance C, we should have

$$MC(T-\theta) + pc(T-\theta) = A(\theta - t);$$

or

$$C = \frac{A(\theta - t) - pc(T-\theta)}{M(T-\theta)}$$

In giving the calculation in this very simple form, we are assuming that the constant A includes not merely the actual water in the calorimeter, but also the "water-equivalents" of the brass of which the calorimeter is composed, and of the glass and mercury composing the thermometer t, for these are all heated at the same time as the water, and to the same extent. If the weight of brass in the calorimeter were w, and the weights of glass and mercury in the thermometer t respectively w' and w'', and if, further, the specific heats of brass, glass, and mercury be c, c', and c'', the "water-equivalent" of the calorimeter (or the quantity of water which would require the same quantity of heat to raise its temperature one degree) would be wc, and the "water-equivalent" of the thermometer t would be $w'c' + w''c''$. Hence if a be the weight of actual water in the calorimeter, the calorimetric value of the whole quantity of matter to which the heat of the body under experiment is imparted will be:

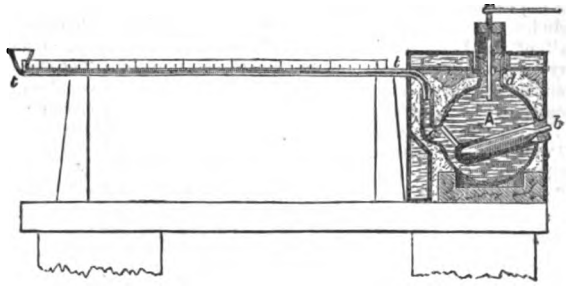
$$A = a + wc + w'c' + w''c''.$$

The values of the several terms making up the whole value of A must obviously be determined by preliminary experiments.

An additional correction, the value of which has also to be found by preliminary trials, is required to compensate the heating or cooling effect of the atmosphere upon the calorimeter and its contents during the course of an experiment. But as the difference between the two temperatures t and θ of the calorimeter seldom exceeds 4° or 5°, it is easy, by keeping the temperature of the instrument as much below the atmospheric temperature during the first half of the experiment as it is expected to exceed it in the second half, to render the error introduced by atmospheric heating or cooling, very small indeed: in Regnault's experiments, it amounted to only three or four hundredths of a degree, but was nevertheless carefully allowed for.

By means of the apparatus above described, the substance under examination can never be heated quite to the boiling point of the liquid in the boiler V, so that when this is water, the temperature of the substance never rises above 97° or 98°; but any other temperature that may be desired can easily be attained by introducing into the boiler, in place of water, a liquid which boils at nearly the required temperature, and then raising or lowering its temperature of ebullition as much as may be needed, by connecting the tube h i with a large reservoir of compressed or rarefied air.

In determining the specific heat of substances (such as phosphorus, for example) which could not be heated without causing them to melt or else to undergo other alterations which would interfere with the accuracy of the results, Regnault adopted an inverse process, and cooled them to a temperature considerably below that of the water in the calorimeter, and thus observed the diminution in the temperature of the latter which resulted from immersing the cooled substances in it. The apparatus employed for producing and maintaining constant a low temperature, resembles to some extent the heating apparatus already described and figured. It consists of a central tube, in the middle of which is suspended the substance to be cooled, surrounded by two larger concentric cylinders. The space between the central tube and the next is partially filled with ether or some other volatile liquid, and the space between this tube and the outside one is filled with air. By causing a rapid current of air to traverse the ether, its temperature is gradually lowered, and with an external temperature of 20° C. any temperature not lower than −12° can be maintained constant by properly regulating the flow of air; the lowest temperature that can be obtained under similar circumstances, by employing sulphide of carbon instead of ether is − 8°. By the use of liquid ammonia, any temperature between −40° and −80° C. can be obtained.



In order to apply the above method to determinations of the specific heat of liquids, they must be enclosed in tubes of very thin glass, nearly filled and hermetically closed. These tubes are suspended, like the basket M, in the centre of the tube A, and afterwards let down into the calorimeter. In calculating the result, allowance must of course be made for the heat imparted to the calorimeter by the tube.

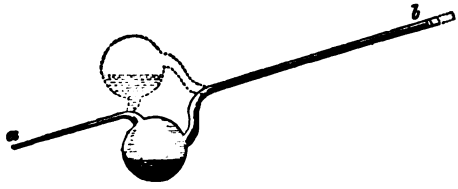
Another apparatus which serves for the determination of specific heats is represented in *fig.* 531. This apparatus, devised by Favre and Silbermann (Ann. Ch. Phys. [3] xxxvi. 33), consists of a glass globe, A, of about 1 litre capacity, in which are three openings. The first, *b*, admits a thin iron or platinum tube, closed at the lower end, about 1 inch (2½ to 3 centimetres) wide and 4 inches (10 or 11 centimetres) long, cemented at the top into the opening of the glass, and kept in its

Digitized by Google

place below by a piece of glass rod, one end of which is cemented against the upper side of the tube and the other end against the side of the glass globe. Within this tube, which is called the *muffle*, is placed another tube of very thin glass which serves to contain the substances under experiment. This is held in its place by a

Fig. 531.

cork which surrounds its neck and fits tightly in the mouth of the muffle; it is surrounded by about 100 grms. of mercury, intended to facilitate interchange of heat between it and the muffle.



The second opening, *c*, carries a horizontal capillary tube, *tt*, about 500 millimetres long, divided into millimetres, and terminated at the farther end by a small funnel. This tube, which should be perfectly cylindrical, is cemented to the glass globe by marine glue, so that, when needful, it can be easily removed and cleaned.

The third opening carries a steel piston, *d*, which, by means of a screw, can be raised or lowered so as to increase or diminish somewhat the capacity of the globe.

The globe itself is supported upon a thick ring of cork and enclosed in a box lined with wadding or swan's-down, and surrounded by a double casing filled with water. It is filled with mercury, with the precautions necessary to exclude any trace of air, and the extremity of the column of mercury is adjusted by moving the steel piston, *d*, up or down, so as to be exactly at the zero point of the divisions of the tube.

In using the instrument, the substance whose specific heat is to be determined, is introduced at a known temperature into the muffle, or into the glass tube inside it. The substance then parts with its heat to the mercury contained in the globe of the calorimeter, causing it to expand, and the expansion read off on the tube *tt* is a measure of the quantity of heat thus imparted to the mercury. In order, however, to compare the indications of this instrument with those of the water-calorimeter, it is needful to know the number of divisions of the tube *tt* which correspond to the effect of a unit of heat, or gramme-degree. For this purpose Favre and Silbermann graduated their instrument as follows:—A few scraps of platinum wire, and 4 or 5 grammes of distilled water, are placed in a pipette of the form shown in *fig.* 532. The pipette is heated over a spirit-lamp until the water boils, the flame being occasionally passed along the point *a*, so as to heat it sufficiently to prevent the condensation of steam, and the drop of water is removed from the end by a piece of filter-paper, so that the steam may have free issue into the air at the moment of beginning the experiment.

Fig. 532.

The lamp is then removed for an instant; the ebullition ceases, and at the same moment the point of the pipette is rapidly introduced to the bottom of the tube contained in the muffle, the pipette being simultaneously turned round through 180° about the axis *ab*. The lamp is then again brought near the pipette, and the cork which closes the upper end is removed, so that no steam may follow the water into the muffle. As soon as the mercury-column in *tt* has reached the extreme point, the temperature of the water is taken by a small and sensitive thermometer; and the experiment is completed by weighing the glass tube with the water contained in it.

If the weight of water be P, and the number of degrees through which its temperature falls after being introduced into the tube of the muffle be T, the number of units of heat imparted to the calorimeter will be PT. If this quantity of heat causes the mercury to advance through N divisions of the tube *tt*, the amount of

Digitized by Google

expansion, C, expressed in the same divisions, corresponding to one unit of heat will be

$$C = \frac{N}{PT}.$$

Favre and Silbermann found that, in the instrument employed by them, one unit of heat caused the mercury to advance in *tt* by 0·3 millimetre.

In determining the specific heats of liquid substances by means of this apparatus, they are introduced into the tube of the muffle by means of the pipette *ab*, in the manner already described in the case of water, the weight employed being determined after the experiment.

Another method of ascertaining the specific heats of various substances consists in determining the quantity of ice which can be melted by the heat given off by a known weight of each while cooling through the same number of degrees. A known weight of the substance to be operated upon is heated to a determinate temperature, as 100°, and then placed in a cavity scooped out of a block of melting ice and covered by a second slab of ice. The temperature of the substance is thus brought down to that of melting ice, and a quantity of ice is melted—that is, a quantity of water is formed—proportionate to the quantity of heat which the substance gives out in cooling to this temperature.

This method, however, though very simple both in principle and in execution, cannot be made to give very accurate results; for there is great difficulty in determining with exactness the quantity of water formed, and a small error committed here will introduce a large error into the estimate of the quantity of heat given out by the body in cooling, since as will be seen hereafter, the quantity of heat needed to convert one part of ice into water would be sufficient to raise the temperature of 79¼ parts of water one degree.

A third method, called the method of cooling, was employed by Dulong and Petit. It consists in determining the length of time which the different substances to be examined require in order to cool in a vacuum from one known temperature to another, each being placed, as nearly as possible, under identical circumstances.

In order to realise the necessary conditions for determinations of this kind, the substances to be examined are all reduced to an impalpable powder, and filled successively into the same cylindrical silver vessel, gilded and highly polished externally, in the axis of which is the bulb of the thermometer by which the progress of the cooling is to be shown. The silver vessel, supported by the stem of the thermometer, is suspended in the middle of a large brass receiver, coated internally with lamp-black, from which the air can be completely removed. This is immersed in water at 40° C., and when the thermometer inside the apparatus marks 35°, it is transferred to melting ice. The thermometer is now watched through a telescope, and the instants at which it marks 20°, 15°, 10°, and 5°, are noted. If all other circumstances were the same, the time during which each substance underwent the same fall of temperature, would be a measure of the amount of heat given out in undergoing this change—that is, of the specific heat of the substance; but Regnault, who submitted this method to very careful examination (Ann. Ch. Phys. [3] ix. 327), found that it was impossible to obtain results of any value by its application in the case of solid bodies: with liquids, for which the same sources of error do not occur as for solids, it is capable of giving much more exact results.

The difficulties attendant on the exact determination of the specific heats of gases and vapours are very much greater than in the case of solids and liquids. An extensive series of experiments on this subject has been made by Regnault (Mém. de l' Acad. des Sciences, xxvi. 41) with elaborate care, the principle of his method being to observe the alteration of the temperature of water, surrounding a spiral tube, caused by the passage through the tube of a known quantity of gas which enters and issues from it at known temperatures. A description of the apparatus employed in these researches and of the methods of experimenting would occupy too much space to admit of its being given here; we must therefore refer for details to the paper already quoted. (A figure of the apparatus and a tolerably full account of the method of experimenting are also given in Daguin's *Traité de Physique*, 2nd edit. ii. 275–280.) The principal results obtained are enumerated below (p. 35).

In the following Table are given the specific heats of a considerable number of the elementary bodies, according to the results obtained by Regnault by the method of mixtures. When the specific heat of the same element has been determined by him several times, the most recent result is given in the Table. The third column gives the temperatures between which the specific heats given in the second column were observed; the numbers contained in the fourth and fifth columns will be referred to presently. The specific heats of the gaseous elements are not included in this table, but will be found in a subsequent one, together with the specific heats of some other gases (see p. 35).

The following short table gives the specific heats of a few substances which require to be taken into account in calculating the results of the experiments from which the numbers in the foregoing and subsequent tables are deduced:—

Name of Substance.	Specific heat.	Temperatures between which the specific heat was observed.
Brass	0·09391	98° and 12°
Glass	0·19768	99 „ 14
Oil of turpentine	0·42593	98 „ 15
Water	1·00800	98 „ 13

Numerous determinations have been made by Regnault of the specific heats of inorganic compounds. A selection from his results, sufficient to show their general nature, is given in the next table. The temperatures between which the determinations were made are not given in the table, but were in all cases a temperature approaching 100° C., and a temperature near that of the atmosphere. In the case of substances which are soluble in water, or capable of being chemically acted on by it in any way, the calorimeter was filled with oil of turpentine. The different substances enumerated in the table are arranged in groups according to their chemical composition.

For a numerous series of determinations of the specific heats of the isomorphous sulphates of the magnesian group, see Pape (Pogg. Ann. cxx. 337).

With regard to alloys of two or more metals, Regnault found that, at temperatures considerably removed from their melting points, their specific heats are the means of the specific heats of their components. In the following table, the values given in the column headed "Calculated Specific Heats" are obtained by multiplying the specific heat of each constituent into the percentage amount of it contained in the alloy, and dividing the sum of all these products for each alloy by 100; these values, therefore, would exactly represent the specific heats of the respective alloys if the above rule were rigorously true; the correspondence between them and the results of direct observation is sufficient to show that the rule is, at least, a close approximation to the truth.

Specific Heat of Alloys.

Composition of Alloy.	Observed specific heat.	Calculated specific heat.
1 at. lead + 1 at. tin	0·04073	0·04039
1 „ + 2 at. tin	·04506	·04461
1 „ + 1 at. antimony	·03880	·03883
1 at. bismuth + 1 at. tin	·04000	·03987

1 „ + 2 at. tin + 1 at. antimony .	·04621	·04564
1 „ + 2 at. tin + 1 at. antimony + 2 at. zinc . . .	·05657	·05479

In the case of alloys which, at the temperature of observation, were approaching their melting points, the observed specific heat was always considerably higher than that calculated as above.

The specific heats of a few liquids are included in the tables already given (pp. 30 and 32): we append here the results obtained by Person (Ann. Ch. Phys. [3] xxi. 333; xxiv. 136), H. Kopp (Pogg. Ann. lxxv. 98) and Favre and Silbermann (Comptes rend. xxiii. 524; also Ann. Ch. Phys. [3] xxxvii. 464–470) for some additional liquids, simple and compound. Favre and Silbermann's experiments were made by cooling the liquids in the mercurial calorimeter (p. 28), from their respective boiling points to temperatures nearly equal to that of the surrounding atmosphere.

The specific heat of water at different temperatures has been determined by Regnault (Mém. Acad. Sciences, xxi. 729) from whose experiments it appears that the quantity of heat expressed in *heat-units* which one gramme of water loses in cooling down from $t°$ to 0° C. is given by the formula,—

$$Q = t + 0{\cdot}00002\,t^2 + 0{\cdot}0000003\,t^3;$$

and the specific heat C at the temperature $t°$, that is to say, the quantity of heat required to raise one gramme of water from $t°$ to $(t + 1)°$, by the formula,—

$$C = 1 + 0{\cdot}00004\,t + 0{\cdot}0000009\,t^2.$$

From this formula, the following numbers are obtained:

Specific Heat of Water.

t.	Q.	C.	t.	Q.	C.
0°	0·000	1·0000	150°	151·462	1·0262
50	50·087	1·0042	200	203·200	1·0440
100	100·500	1·0130	230	234·708	1·0568

The specific heat of ice is considerably less than that of liquid water. According to Regnault's experiments, it is 0·474 between −78° and 0° C., and 0·504 between −20° and 0°, according to the experiments of Person and of Desains.

It results from Regnault's determinations of the specific heats of gases and vapours, made in the manner already mentioned (p. 29), that the specific heat of a given *weight* of a gas which obeys Boyle's law (Gases, ii. 820) does not alter with variations either of temperature or of pressure. This was found to be true of atmospheric air

Digitized by Google

between the temperatures of − 20° and + 225°, and at pressures varying from 1 to 12 atmospheres. Consequently the specific heat of a given *volume* of air, or other non-condensable gas, varies directly as its density. In gases which do not follow Boyle's law, this regularity does not exist: thus the specific heat of carbonic anhydride is found to increase perceptibly as its temperature rises, being 0·18427 between −30° and 10°, and 0·20246 between 10° and 100°, and 0·21692 between 10° and 210°, as compared with that of an equal weight of water.

The following table gives the specific heats of the various gases and vapours examined by Regnault, compared, first, with an equal weight of water taken as unity, secondly, with that of an equal volume of air referred as before to its own weight of water as unity. The latter series of numbers is obtained by multiplying the numbers expressing the specific heats of equal weights of the various gases or vapours, by their respective densities referred to that of air as 1.

Comparing these values with those given for some of the same substances in previous tables, it appears that the specific heat of the same body is commonly greater in the liquid than in the solid state, and always less in the gaseous than in the liquid state.

On examining the numbers above given for the specific heats of different bodies, it will be seen that the specific heat of a substance is not altogether an absolute and unchangeable property: on the contrary, it will be evident that this property, in one and the same substance, is capable of considerable variation, depending (*a*) on the

Digitized by Google

physical structure of the substance, (*b*) on its temperature, (*c*) on its state of aggreg tion. In illustration of this remark, it will be sufficient to refer to the specific heats carbon, silicon, selenium, sulphur, phosphorus, alumina, and carbonate of calcium, given in the foregoing tables, in evidence of the influence of differences of physic condition; to the specific heats of lead, phosphorus, water, and ice, in evidence of t effect of differences of temperature; and to those of bromine, mercury, tin, lead, bismut water, &c., in the solid and liquid states, in evidence of the effect of the state of aggr gation.

In reference to the connection between specific heat and temperature, it may remarked that this property varies to a greater extent, for a given interval of temp rature, near the temperatures at which changes in the state of aggregation occu than at a distance from those temperatures. Thus, the specific heat of lead, an easi fusible metal, is considerably greater between 10° and 100° C. (=0·0314) than it between 10° and −78° C. (=0·0306); and that of phosphorus, a still more fusib substance, shows even a greater difference when compared between 10° and 3 (specific heat = 0·1887) and between −71° and 10° C. (specific heat = 0·1740 while the specific heat of platinum, one of the most infusible of all the metals, vari to a scarcely perceptible extent at temperatures below 100° C., and only slowly temperatures considerably higher. The mean specific heat of this metal between 0° and the temperatures enumerated below, was in fact found by Pouillet to be repr sented by the numbers contained in the second line of the following table.

Specific Heat of Platinum.

Interval of temperature	0° and 100°	0° and 300°	0° and 500°	0° and 700°	0° and 1000°	0° and 1200
Mean specific heat .	0·0335	0·03434	0·03518	0·03602	0·03728	0·03806

The specific heat of solid bodies therefore increases with rise of temperature, up their melting points, and at this temperature there is generally a further sudd increase of specific heat of a considerable amount.

It may be further noticed that in the table of the specific heats of the elemen (p. 30), the elements are arranged nearly in the order of their specific heats, beginni with lithium (specific heat = 0·941) and ending (if we disregard for the present t three elements carbon, boron, and silicon, which are placed together after the rest) wi bismuth (specific heat 0·031); and that this order is also exactly the inverse order of th atomic weights, as given in the fourth column, the atomic weight of lithium (= being less than that of any other element included in the table, and that of bismu (= 210) being greater than that of any other element. In fact, not only do thc elements whose atomic weight is lowest possess, as a rule, the greatest specific he and *vice versâ*, but the specific heats of the elements (in the solid state) are, with comparatively narrow limits, inversely proportional to their atomic weights, wh these are taken as having the values given in the fourth column of the table; so th the product of the specific heats of the elements into their atomic weights is nearly constant quantity; as shown by the numbers in the fifth column of the table. Th numbers may be taken to represent the *atomic heats* of the elements, or the relati quantities of heat which must be imparted to, or removed from, atomic proportions the several elements, in order to cause in them equal alterations of temperature. T table shows that the atomic heats of the elements are not represented by an absolut constant quantity: but when it is considered that the two factors (atomic weight a specific heat) of which they are made up, vary in the proportion of 1 : 30, it cannot denied that they are comprised between comparatively very narrow limits: for (taki those determinations only which refer to comparable conditions of the several elemen and which there is reason to believe were made upon nearly pure substances) we fi that they are nearly all included between 5·9 (aluminium, rhodium) and 6·9 (iodin the greater number not differing much from 6·5. (The high atomic heat of uraniu 7·4, is doubtless to be explained by the impurity of the metal operated upon.) T general accordance is amply sufficient to indicate the existence of a general la although the individual results show the effect of some one or more disturbing caus And even if it be admitted that the true atomic heats of the elements under conside tion are really identical, under comparable circumstances, there are several reasons w the experimental atomic heats, deduced like those in the foregoing table, cannot expected to exhibit the same identity. The most important of these reasons are: t unavoidable experimental errors attaching to the determination of the specific heat the imperfect purity of some of the elements examined; the circumstance that, althou most of the determinations were made at nearly the same absolute temperatures—name between a temperature near 100° and that of the atmosphere—the different elemei

Digitized by Google

are not, in regard to their specific heats, under comparable circumstances at these temperatures, some being much nearer to their melting point than others, and therefore having in general relatively higher specific heats (see p. 36); lastly, in a few cases, the uncertainty of the experimental data used in fixing the atomic weights.

The relation of approximate equality among the atomic heats of the elements exists, however, only when their atomic weights are allowed to have the values given in the table: these values are in very many cases the double of those given in the table of atomic weights, vol. i. pp. 464, 465, and employed in the first edition of this work. If the latter scale of atomic weights be adopted, the elements would have to be divided into two classes: those whose atomic heat is approximately 6·5, and those whose atomic heat is approximately 3·2. The fact that, by doubling the atomic weights of the latter class of elements, their atomic heats would be brought into harmony with those of the former class, is in itself a strong argument in favour of such a change; and by reference to the articles ATOMIC WEIGHTS (i. 468–473) and CLASSIFICATION (i. 1008, 1009, foot-note) and the article ATOMICITY in the SUPPLEMENT, it will be seen that it is supported by many other considerations, both chemical and physical. In any case it is certain that the numbers in the column headed "Atomic Weights," in the table on p. 30, represent quantities of the various elements which are calorimetrically comparable; and it is therefore best to assume these numbers as really representing those weights of the elements which, in relation to the phenomena of heat, possess the properties of atoms. Whether the chemical atoms of the elements are always identical with the calorimetric atoms, is a question that is perhaps still open to discussion.

It is very important, however, not to overlook the fact that the atomic heats of boron, carbon, and silicon form unquestionable exceptions to the general rule, and cannot be brought into harmony with it, by the adoption of any atomic weights to which the present state of chemical knowledge lends any serious support.

The examples which have been given (pp. 31–33) of the specific heats of compound bodies, show that, within certain classes of allied compounds, the same kind of relation subsists between their specific heats and molecular weights, as has been pointed out between the specific heats and atomic weights of the elements. Consequently, the molecular heats of the substances comprised in each such class, or the products of their specific heats into their molecular weights (see the last column of the table), are approximately equal. In calculating these molecular heats, the atomic weights of the elements are taken as having the values which may be deduced from their specific heats; those values, namely, which are given in the previous table. Adopting these atomic weights, it will be seen that, as a rule, the molecular heat of solid compound bodies increases with the number of atoms contained in their molecule. For instance, the molecular heat of the oxides MO enumerated in the table averages about 11; that of the oxides MO^2, about 14; that of the oxides MO^3, about 19; that of the oxides M^2O^3, about 25·5.

An extensive series of determinations of the specific heats of solid bodies has been made by H. Kopp, but the individual results have not yet been published (1864); we shall, therefore, instead of discussing any further the relations between specific heat and chemical composition which might be deduced from Regnault's experiments already given, reproduce here the substance of the remarks which Kopp (Ann. Ch. Pharm. cxxvi. 362), with his own results before him, makes upon this subject.

This new investigation has brought to light a considerable number of additional examples of solid compounds which, having an analogous atomic constitution, possess also approximately the same molecular heat. Among these, particular interest attaches to the case in which an analogy of constitution is apparent only when the atomic weights of the elements are admitted to have the values assigned to them in the foregoing tables, and where the formulæ previously adopted and the old atomic weights of the elements would never have caused any such relations between specific heat and molecular weight to be suspected. Just as the molecular heats of carbonates and silicates, $M''CO^3$ and $M''SiO^3$, and of nitrates and chlorates, MNO^3 and $MClO^3$, are approximately equal, so also are the molecular heats of the permanganates and perchlorates, $MMnO^4$ and $MClO^4$, and of the sulphates and chromates, $M''SO^4$ and $M''CrO^4$. The new investigation, however, also furnishes some additional examples to the previously known exceptions to the general rule, and thus supplies further evidence of the fact that it is possible for bodies of analogous constitution to differ considerably in their molecular heats.

The molecular heat of a compound appears to be governed only by its empirical, and not by its rational constitution. Analogous compounds, in one of which a complex group occupies the place of an elementary atom, were found, even when isomorphous,

Digitized by Google

to have unequal molecular heats; thus the molecular heats of the ammonium-compounds are considerably greater than those of the corresponding potassium-compounds, and those of the cyanogen-compounds exceed those of the chlorine-compounds.

The atomic (or molecular) heat of any body which is contained in a compound, or may be assumed as one of its constituents, may accordingly be ascertained indirectly, by deducting from the molecular heat of the compound that of whatever other constituents it contains in addition to the body in question. For instance, if we deduct from the molecular heat of a compound of the form $M^{VI}M''O^4$ (chromate of lead, tungstate of calcium, &c.)—which, it may be remarked, is twice as great as that of compounds of the form $M^{IV}O^2$ (stannic oxide, titanic anhydride, &c.)—the molecular heat of the base M''O, we get as remainder the molecular heat of the anhydrous acid $M^{VI}O^3$; and the same remainder is obtained by deducting, from the molecular heat of acid chromate of potassium, $K^2Cr^2O^7$, that of the neutral chromate, K^2CrO^4. Again: the molecular heats of hydrated compounds admit of being regarded as made up of the molecular heat of the respective anhydrous substances, together with that of the water contained in them in the solid form.

Such indirect determinations of the atomic heat of a substance are nevertheless somewhat uncertain: not only because it occasionally happens that analogous compounds, which there is every reason to expect would possess equal molecular heats, do nevertheless, according to the experimental determinations of their specific heats, show important differences in their molecular heats; but also, and more particularly, because the total uncertainty attaching to the determination of the molecular heat, both of the original compound and of the element or group which has to be deducted from it, is accumulated upon the relatively small remainder. But when such inferential determinations are made for whole series of corresponding bodies, and not merely for individual cases, the results may be regarded as sufficiently trustworthy to render such considerations as arise from them worthy of notice.

This is especially the case with regard to the inferred specific and atomic heats of certain elements. As already pointed out, nearly all the elements, when examined in the solid state, are found to have approximately the same atomic heat—on the average, about 6·4. It is now very generally admitted that this—the so-called law of Dulong and Petit—holds good for *all* the elements, and a scale of atomic weights of the elements is considered as satisfactorily established if the products of these atomic weights into the specific heats are nearly equal. In the case of some elements, however, it results, both from the older determinations of their specific heats and from Kopp's newer determinations, that this rule is inapplicable; for example, the specific heats of carbon, boron, and silicon, are such, that the products, obtained by multiplying them into the respective atomic weights—when any values are adopted for these which can possibly be deduced from chemical considerations—are always decidedly smaller than the corresponding products in the case of other elements whose specific heats in the solid state can be investigated.

But these exceptional or accidental results acquire additional interest when taken in connection with the conclusions which may be drawn from the molecular heats of compounds. Compounds of those elements which obey Dulong and Petit's law exhibit a regularity in their molecular heats (*A. H.*): such, namely, that these are as many times greater than that of an element, as there are elementary atoms contained in the respective compounds (that is to say, $\frac{A.H.}{n} = 6{\cdot}4$ nearly, if n denotes the number of elementary atoms in one molecule of each compound). This regularity appears, not only in alloys containing atomic proportions of different metals, but also in the metallic chlorides, bromides, and iodides (see table, pp. 31, 32), and has been found by Kopp to extend likewise to compounds of which one molecule contains as many as seven, or even nine, elementary atoms (such as ZnK^2Cl^4 and PtK^2Cl^6). It is less distinctly recognisable in the case of the compounds of the metals with sulphur ($\frac{A.H.}{n}$ is here usually less than 6), and no longer exists for the metallic oxides, which, almost without exception, give for the quotient $\frac{A.H.}{n}$ a number decidedly less than 6, and smaller in proportion as the number of oxygen-atoms exceeds that of the atoms of metal. For water, considered of course in the solid state, this quotient is only about 3, and for the few organic compounds which Kopp has examined (such as tartaric acid and cane-sugar) it is still less.

The fact that this regularity is absent in so many compounds admits of only one explanation—namely, that they contain elements which, at least in these combinations, possess a different atomic heat from that which corresponds to Dulong and Petit's law.

It has often been assumed that the specific, and therefore the atomic, heat of an ele-

Digitized by Google

ment may be different in certain compounds from what it is in the free state, and that it may be different in one compound from what it is in another. But, according to Kopp, the only ground for such an assumption is that by means of it the calculated molecular heats of compound bodies can be brought into closer agreement with the results of experiment; for, as he remarks, the variations which the specific heat of an element must be supposed capable of undergoing when it enters into combination (if Dulong and Petit's law be taken as applicable to all elements in the free state) are much greater than the variations, dependent on differences of physical condition, which have ever been actually observed in the case of an accurately investigated element. On the contrary, it appears that, in many compounds, the elementary atoms of which they are composed retain the atomic heats which belong to them in the free state; and that, moreover, the atomic heats which can be indirectly calculated for certain elements, notwithstanding their disagreement with Dulong and Petit's law, accord very closely with the atomic heats which result from the direct investigation of the same elements in the free state. Kopp accordingly maintains that—although these last-mentioned facts render the calculation of the molecular heat, and thence of the specific heat, of compound bodies from the atomic heats of the elements much more difficult, and although they make the agreement between the results of calculation and those of direct observation much less complete—every element, when considered in the solid state, and at a temperature sufficiently removed from its melting point, possesses one essentially invariable specific heat, which it is true may vary somewhat with differences of physical condition—such as greater or less density, amorphous or crystalline structure, &c.—but not to such an extent as some of his determinations of specific heat would require, if Dulong and Petit's law were really applicable to all the elements; and further, that the specific heat of each element in the free state is essentially the same as that which it possesses in its compounds.

By deducting from the molecular heats of the various oxides the atomic heats of the metals contained in them, or by deducting from the molecular heats of the oxygen-salts those of the groups which are therein united with oxygen (taking away from the molecular heat of $KClO^3$, for example, that of KCl, or from that of $PbSO^4$ the molecular heat of PbS), a remainder is obtained in every case which gives for the atomic heat of oxygen a number less than 6. For the reasons already stated (p. 38), the results thus arrived at do not agree so well as might be wished; nevertheless, Kopp gives it as his opinion that the atomic heat of oxygen cannot differ greatly from 4.

When the molecular heats of the carbonates M^2CO^3 and $M''CO^3$ are compared with the molecular heats of the oxides $(M'')^2O^3$ $(=3M''O)$ and $(M''')^2O^3$, the molecular heats of the carbonates are found to be decidedly smaller (according to Regnault's experiments, as given in the table, pp. 31–33, the molecular heats of the carbonates M^2CO^3 and oxides $3M''O$ are, on the average, about 29·4 and 32·85 respectively; those of the carbonates $M''CO^3$ and oxides $(M''')^2O^3$, about 21·7 and 25·5 respectively). Such comparisons show that the atomic heat of carbon in these combinations must be assumed to be about the same as that which has been directly found for free carbon in the form of diamond; namely, 1·8. Similar comparisons applied to other elements lead likewise to the adoption of atomic heats which are much smaller than what would correspond to the law of Dulong and Petit: for instance, to the atomic heat 2·3 (nearly) for hydrogen; for boron, to a number lying between 2 and 3; for silicon, to 4 (nearly); and for fluorine, also to a number which appears to be distinctly less than 6·4.

The specific and molecular heats of compound bodies calculated with the atomic heats thus arrived at for the elements, show, in very many cases, a very satisfactory degree of agreement with those deduced from direct experiment; in many other cases, however, they show important discrepancies. But equal discrepancies may likewise be observed among the molecular heats of analogous compounds, such even as contain elements as corresponding constituents which, when examined in the free state, gave nearly equal atomic heats. Regnault not unfrequently found this difference amount to one-tenth of the molecular heats in question; occasionally it was still greater.

Kopp considers that the results of his investigation confirm and widen the conclusion, already adopted by some philosophers, that Dulong and Petit's law does not hold good for all the so-called elements in the solid state. For a particular group of elements it is undoubtedly true; but if it is not a universal law, and if there are some elements to which it certainly does not apply, it may be considered doubtful with regard to individual elements, whether they ought to be looked upon as agreeing with or as departing from it. This may be said to be the case with sulphur, for which Kopp's determinations, made between 47° and the temperature of the atmosphere, give the atomic heat 5·2, nearly, which likewise agrees with the atomic heat of sulphur as indirectly deduced from the molecular heats of the metallic sulphides.

Digitized by Google

In general, the molecular heat of a compound increases with its degree of complexity, or with the number of elementary atoms contained in one molecule, and this more especially in the case of such as contain only elements which follow Dulong and Petit's law. Kopp points out that if the application of this rule be extended to the elements themselves, the fact that a large proportion of them have nearly the same atomic heat may be taken as an indication that, whether they be absolutely simple substances or no, they are at least bodies of a comparable degree of complexity; while, on the other hand, the smaller atomic heats of some elements would seem to show that they are of a lower degree of complexity, or approach more nearly to truly simple bodies, than the rest. It would thus appear to be possible for a substance which can be proved to be compound, to have the same atomic heat as a so-called element: for instance, a peroxide, XO, containing an element whose atomic heat was equal to that of hydrogen, namely, about 2·3, would have a molecular heat of about 2·3 + 4 = 6·3, that is to say, the same as that of chlorine, iodine, or the metals.

With regard to the apparent improbability of two so-called elements, which are capable of mutually replacing each other in compounds, like hydrogen and the metals—or which even appear as corresponding constituents of isomorphous substances, like silicon and tin—having unequal atomic heats, it must be borne in mind that this is not in reality any more surprising or improbable than that an undecomposible substance and one known to be compound, such, for example, as hydrogen and peroxide of nitrogen, or potassium and ammonium, should replace each other in compound bodies without causing any alteration in their chemical characters, or should even be capable of appearing as corresponding constituents of isomorphous substances.

It still remains to consider, rather more particularly than has been done thus far, what it is that is measured under the name of the specific heat of solid, liquid, or gaseous substances, by the methods above described.

In all these methods of measurement, the heat imparted to the various bodies does something more than merely raise their temperature: it causes at the same time, as will be seen by what follows, an expansion or increase of their bulk; and when the bodies are again cooled, they contract, or diminish in bulk, to an equal amount. Hence the specific heats, measured as above, are not, strictly speaking, the relative quantities of heat required to raise the temperature of the various substances to the same extent, but the quantities required to do this, *and* at the same time to cause a greater or less increase of bulk. It is therefore a question for further investigation, what proportion of the total specific heat of a substance goes to raise its temperature, and what proportion to cause it to expand, or possibly to modify it in other ways.

The expansion which accompanies a given rise of temperature is inconsiderable in the case of solids and liquids, compared with that which takes place in gases; but it would be incorrect to conclude that the proportion of the total specific heat of solid, liquid and gaseous substances respectively, which is expended in causing expansion, is in proportion to the amount of expansion actually produced in each case. On the other hand, although no data exist which make it possible to form a very definite estimate of the ratio of the *real* specific heat to the *total apparent* specific heat of solids or liquids (see, however, p. 44), it is certain that they oppose a much greater resistance to any force tending to alter their bulk than gases do, and hence the comparatively small amount of expansion which they undergo may require the expenditure of as much or more heat than the relatively great expansion which takes place in gases: there is, therefore, no reason to believe that the ratio of the two specific heats, in the case of solid and liquid substances, is a magnitude of a different order from what it is in the case of gases.

The ratio of the apparent to the real specific heat of a gas, is the ratio of its specific heat under constant pressure (when, therefore, it expands as the temperature rises) to its specific heat when kept at a constant volume. It is, of course, the specific heat under constant pressure which is determined by the method already described (p. 29), and which is given for several gases in one of the preceding tables (p. 35). That the specific heat of a gas kept at a constant volume is less than its specific heat under a constant pressure, is obvious from the following considerations. Suppose a quantity of gas to have had its temperature raised t°, while the pressure to which it was exposed remained constant: the increase of temperature will have been accompanied by a corresponding increase of volume. Now, suppose the gas to be compressed, so as to restore it to its original bulk: the result of this compression will be to raise its temperature t'° more. The gas will now be in the same condition as it would have been if the same quantity of heat had been imparted to it without its being allowed to expand: hence it is evident that the same quantity of heat that is required to raise the temperature of a given weight of gas t°, while the pressure remains constant, will suffice to raise the temperature of the gas $t + t'$ degrees if it

Digitized by Google

is kept at a constant volume. The specific heat, c', corresponding to a constant pressure, is therefore to the specific heat, c, corresponding to a constant volume, as $t + t'$ to t. One gramme of air has its temperature raised 1° C. when there is imparted to it 0·2374 of a unit (gramme-degree) of heat, and it expands at the same time, if the pressure remains unaltered, by $\frac{1}{273}$ of its bulk at 0° C. Accordingly, if the elevation of temperature consequent on compressing a gas by $\frac{1}{273}$ of its bulk at 0° be $a°$, it is evident that the ratio

$$\frac{1 + a}{1} = \frac{c'}{c} = k$$

is the ratio of the specific heat under constant pressure to that at constant volume. Clement and Desormes found by direct experiments upon air the value 0·34° for a, but it is plain that the unavoidable loss of heat attending such experiments must cause the result to be too low.

A less direct, but far more accurate means of determining the ratio $k = \frac{c'}{c}$, not only for air but for several other gases also, is afforded by the theory of the propagation of sound. The velocity with which a wave-motion, such as that which constitutes sound, is propagated through a homogeneous medium whose elasticity is the same in all directions, depends only upon the elasticity, e (see ii. 370), and the density, d, of the medium, according to the equation

$$v = \sqrt{\frac{e}{d}}.$$

This expression, applied to the movement of a sound-wave through the air, becomes

$$v = \sqrt{\frac{e}{d}} = \sqrt{\frac{gH\sigma}{s} \cdot k\,(1 + a\,t)};$$

where g denotes the accelerating force of gravity (= 9·808 metres = 32·18 feet); H = 760 mm. = 29·92 inches; σ the weight of 1 cub. cent. of mercury at 0° = 13·596 grm.; s the weight of 1 cub. cent. of air at 0° and under a pressure of 760 mm. mercury = 0·001293 grm.; t the temperature of the air, a its coefficient of expansion under constant pressure (= 0·00367), and k the required ratio $\frac{c'}{c}$. Now the velocity of sound in air at 0° has been experimentally found to be = 333 metres, or 1092·6 feet per second; hence the above equation gives

$$333 = \sqrt{\frac{9·808 \times 0·76 \times 13·596}{0·001293} \cdot k}$$

or k = 1·414.

The physical reason for the presence of the magnitude k in the formula for the velocity of sound, is that that velocity, being dependent upon the elasticity of the air, varies with every variation of the elasticity, and that the alternate heatings and coolings, caused respectively by the alternate condensations and rarefactions which constitute the waves of sound, are equivalent, in their effect upon the velocity of transmission of the waves, to an increase in the elasticity of the air in the proportion of $1 : k = 1 : 1·414$.

In the above formula the magnitudes g, H, σ t, and a are all independent of the particular nature of the gas (at least in the case of perfect gases; for imperfect gases the value of a varies slightly), hence if v and v' represent the velocities with which sound traverses two different gases, s and s' their densities, and k and k' the ratios of the two specific heats of each, we have

$$v : v' = \sqrt{\frac{k}{s}} : \sqrt{\frac{k'}{s'}},$$

or

$$\sqrt{k'} = \frac{v'}{v}\sqrt{\frac{s'}{s}} \cdot k;$$

so that the ratio k' for any gas may be deduced from that of air, provided the density of the gas and the velocity with which it is traversed by sound are known.

Hence the investigation of this ratio is reduced to that of the real velocities of sound in different elastic fluids. For any other gas than atmospheric air, it is useless to think of measuring directly the velocity of propagation of a sonorous wave; recourse must obviously be had to indirect means. The theory of wind instruments suggested a mode, which was first indicated and put in practice by Chladni and Jacquin. This method consists in making the same pipe, with a flute *embouchure*, sound successively with all the elastic fluids, supposed at the same temperature, and in determining the

Digitized by Google

pitch of tone given by each gas. Admitting that the fluid column contained in the instrument experiences the same mode of subdivision in every case—that it corresponds, for example, to what is called the fundamental sound, or the gravest of all those which the theory of Bernouilli indicates for the same pipe, we easily come to know the length of a wave, and its duration in each elastic fluid; and consequently the velocity with which a vibration would be propagated in each of them.

The following table exhibits the results of Dulong's researches on this subject. (Ann. Ch. Phys. xli. 113):

Names of the elastic fluids.	Tones given by the same pipe 60 centim. long.	Number of vibrations in a sexagesimal second.	Temperature by the centigrade therm.	Numbers adopted in the calculation for the density of the fluid.	Velocity of the propagation of sound at 0°, deduced from the tone given by each fluid.	Ratio of the specific heats at a constant pressure, to the specific heat at a constant volume, $= k$.

Olefiant gas .	$-si_{-1}$	466·9	16	0·981	314	1·240

The slight difference between the value 1·421, obtained by Dulong for the ratio of the two specific heats of air, and the number 1·414 already given is, in part, due to the changes which have taken place, since the date of his experiments, in the adopted value of the constants which enter into the calculation.

Theoretical views of the nature of heat and the constitution of gaseous bodies, which will have to be further considered in a subsequent part of this article, lead to the conclusion that, for all perfect gases, the difference between the two specific heats of a unit of volume is expressed by the equation

$$\gamma' - \gamma = A \frac{p}{a + t} \quad . \quad . \quad . \quad . \quad . \quad (a)$$

where A is a constant (the thermal equivalent of the unit of work), p and t the pressure and temperature of the gas, and $\frac{1}{a}$ the coefficient of expansion, and therefore $a = 273$ nearly. The right hand member of this equation contains nothing which depends on the particular nature of the gas to which it is applied; and hence, if the temperature and pressure are taken the same for all gases, the difference $\gamma' - \gamma$ will be the same for all. If the values of γ' and γ applicable to atmospheric air be distinguished as γ_1', and γ_1, we have

$$\gamma' - \gamma = \gamma_1' - \gamma_1,$$

an equation which remains true whatever unit of volume is adopted, and therefore also, if with Regnault, we take this unit to be the volume occupied by a unit of weight of air at the same temperature and pressure as the gas under consideration. Therefore

$$\gamma' - \gamma = \gamma_1' - \gamma_1 = 0{\cdot}2374 - 0{\cdot}1680 = 0{\cdot}0694 \text{ and } \gamma = \gamma' - 0{\cdot}0694.$$

By means of this equation, the specific heats of the various gases under constant volume may be calculated from their specific heats under constant pressure as given in the table on p. 35. The numbers so obtained will refer to the unit of volume adopted by Regnault; to deduce therefrom the specific heats which correspond to a *unit of weight*, these numbers require merely to be divided by the densities of the respective gases; and to obtain the specific heats *compared with that of an equal volume of air*, they must be divided by 0·1680.

Digitized by Google

According to equation (*a*) the quotient $\frac{\gamma'}{\gamma} = k$ becomes

$$k = 1 + \frac{A}{\gamma} \cdot \frac{p}{a + t}$$

and it therefore exceeds unity by a quantity which is inversely proportional to γ.

Further, the general considerations above referred to make it probable that the true specific heat of equal volumes of all simple gases is the same, and that the specific heat of compound gases is equal to that of the simple gases multiplied by the fraction which represents their molecular condensation (*e.g.* for hydrochloric acid the multiplier would be $\frac{1+1}{2} = 1$, for water $\frac{2+1}{2} = 1{\cdot}5$, for ammonia $\frac{3+1}{2} = 2$, &c.).

The following table, which is copied with very slight modifications from tables given by Clausius (Ann. Ch. Pharm. cxviii. 118) and Buff (*ibid.* cxv. 312; see also pp. 306, 307), and may be considered supplementary to the table on p. 35, gives the results of the application of these formulæ to the gases and vapours which were the

adopted by Regnault in his calculations. Column IV. gives the specific heats under *constant pressure* compared with that of an equal volume of air taken as unity. The numbers in this column are obtained from those in the last column of the table on p. 35 by dividing each by 0·2374 = specific heat of air under constant pressure. Columns V. and VI. contain the specific heats corresponding to a *constant volume* compared (V.) with that of an equal weight of water, and (VI.) with that of an equal volume of air. Column VII. gives the *ratio of the two specific heats* for some of the most important gases, obtained by dividing the specific heats of equal weights under constant pressure, as given in the previous table (p. 35), by the corresponding values in column V. of this table. Column VIII. contains the theoretical *true specific heats*, compared with the true specific heat of an equal volume of air or any simple gas. These numbers are calculated upon the supposition that the true specific heats of the elementary gases are the same in the combined as in the uncombined state.

On comparing the numbers in columns VI. and VIII. it will be seen that there is, on the whole, an unmistakable correspondence between them, but that they exhibit also in many cases decided discrepancies. These are probably due, in part to errors of experiment, and in part to the fact that the method, by which the numbers representing the specific heats at constant volume are calculated from those representing the specific heats at constant pressure, is quite accurate only in the case of perfect gases; and further that, even if the numbers in column VI. represented the specific heats for constant volume with perfect accuracy, these numbers would not necessarily agree with those in column VIII., except for perfect gases.

The true specific heat of a gas, that is, its specific heat under a constant volume, is regarded by Clausius (Phil. Mag. [4] xxiv. 204, 205) as the true specific heat of the substance in all states of aggregation, and in the combined as well as the free state. Rankine, on the other hand (*A Manual of the Steam Engine*, &c., p. 307), while admitting that the true specific heat of each substance remains constant at all densities, so long as the substance retains the same condition, solid, liquid, or gaseous, supposes that a change of real specific heat, sometimes considerable, often accompanies the change between any two of these conditions. But, as Clausius has pointed out (*loc. cit.*; also Pogg. Ann. cxx. 438), there is no obvious reason why the real specific heat of a body should be supposed to undergo alteration on the passage from one state of aggregation to another, if it remains constant within the same state of aggregation; for the changes of density and elasticity, which accompany changes of temperature within one and the same state, do not differ in kind, but only in degree, from those which constitute the passage from one state to another. Assuming, therefore, that the specific heat under constant volume of a substance in the gaseous state is its real specific heat under all conditions, we have, for water, for instance,

Ratio of apparent to real specific heat in the *solid state* (between $-20°$ and $0°$) . . . . . $= \frac{\cdot 504}{\cdot 369} = 1\cdot 367$

Ratio of apparent to real specific heat in the liquid state (between $0°$ and $100°$) . . . . . $= \frac{1\cdot 008}{\cdot 369} = 2\cdot 732$

Ratio of apparent to real specific heat in the gaseous state . $= \frac{\cdot 4805}{\cdot 369} = 1\cdot 302$

2. *Changes of Volume produced by Heat.*

It is an almost universal law that, when heat is imparted to any body, the body expands or augments in bulk, unless prevented from doing so by a corresponding increase of external pressure, and that any body from which heat is withdrawn contracts or diminishes in bulk. The exceptions to this law are extremely few, and occur only within particular limits of temperature: the most important will be specially pointed out hereafter. Admitting the atomic hypothesis of the constitution of matter, it is impossible to conceive of expansion otherwise than as a movement of the molecules of a mass, which has for its effect to increase their mean distance from each other. Hence when heat causes a body to expand, it acts in opposition to the forces which tend to prevent the further separation of the molecules; and the bulk of the body at any given temperature is the result of an equilibrium between these forces and the expansive force of the heat contained in it at that temperature. The forces by which the particles of a mass are held together consist in part of the pressure to which it is subjected from without, and partly of the pressure arising from the mutual attractions of the particles themselves. This latter pressure, which is known as cohesive force, has a much greater effect in determining the bulk of solid and liquid

Digitized by Google

bodies than any pressure which acts upon them from without, and it varies not only in different bodies, but even in the same body its value is different at different temperatures. Hence it is not surprising that the relations subsisting between the temperature and bulk of solid and liquid substances should be somewhat complex. In perfect gases, however, cohesion does not exist, and hence the only opposing force which heat has to overcome in order to cause them to expand is the external pressure. Consequently it is found that the rate of expansion of gases bears a much more simple relation to the heat by which it is caused, than that observed in solid and liquid bodies. It is, therefore, convenient to consider the laws of the expansion of gaseous substances before examining those which regulate the expansion of matter in the two other states of aggregation.

Expansion of Gases.—In a perfect gas, volume, elasticity, and temperature would be related to each other in the manner expressed by the equation

$$pv = J(a + t), \quad . \quad . \quad . \quad . \quad . \quad . \quad (a)$$

where v is the volume of a given weight of the gas at the temperature t and under the pressure p, and J and a are constants. Hence, if v' were the volume of the same weight of the same gas corresponding to any other pressure, p', and temperature, t', we should have

$$\frac{p\ v}{p'v'} = \frac{a + t}{a + t'} \quad . \quad . \quad . \quad . \quad . \quad (b)$$

No absolutely perfect gas, however, is known in nature, so that, according to the best experiments, the values of a which correspond to different values of p, v, and t, are not quite constant, but vary slightly, not only with variations of these factors, but also according to the nature of the gas. The properties of air, however, and the other non-condensable gases accord so nearly with the above formulæ—which are in fact nothing more than a statement of the laws of Boyle and Gay-Lussac (Gases, ii. 819*)—that, except in cases where extreme accuracy is required, the accord may be considered perfect.

If in the above equation (b) we make $p = p'$ we get

$$\frac{1}{a} = \frac{v - v'}{v't - vt'}; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (c)$$

that is, $\frac{1}{a}$ is the *coefficient of expansion of the gas under constant pressure*, or the amount by which that quantity of gas which occupies a unit of volume at 0° C. expands, under constant pressure, when its temperature is raised one degree. Similarly, by making $v = v'$, we have

$$\frac{1}{a} = \frac{p - p'}{p't - pt'}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (d)$$

or $\frac{1}{a}$ is also the *coefficient of expansion of the gas under constant volume*, or, more correctly (since when $v = v'$ no actual expansion can take place), $\frac{1}{a}$ is the coefficient of increase of elasticity, or the increment of elasticity, under a constant volume, for a rise of temperature of one degree, of a gas whose elasticity at 0° C. is unity. For a perfect gas, it is obvious that these two values of $\frac{1}{a}$ would be equal.

The first tolerably accurate determinations of the coefficients of expansion of gaseous bodies were made by Gay-Lussac. He used in his experiments a vessel shaped much like a thermometer, having a bulb about 1 centimetre in diameter, and a tube about 30 or 40 centimetres long, and 1 or 1·5 millimetres wide. The tube was divided into lengths of equal capacity, and the proportion between the total capacity of the bulb and that of one division of the tube was accurately determined. The apparatus having been filled with air dried by passing through a chloride-of-calcium tube, a drop of mercury, occupying a short length of the divided tube, was employed to cut off the enclosed air from communication with the atmosphere, and at the same time to serve as an index whereby to read off its volume. The bulb was then fixed, with the stem horizontal and projecting through the side, in a vessel filled with water, through the medium of which it could be heated to various temperatures. The volumes occupied by the air at each temperature could be read off upon the divided tube by noting the position of the little column of mercury; but the volumes thus determined required to be corrected (a) for the

* Equation (b) may obviously be put into the form $v = v' \frac{p'}{p} \cdot \frac{a + t}{a + t'}$, and is then identical with that by which these laws are represented at the place quoted.

Digitized by Google

expansion of the glass, (*b*) for the lower temperature of the portion of air contained in the part of the tube outside the water-bath, and (*c*) for the possible alterations of barometric pressure during the experiment. Independently of these latter alterations, which were always very inconsiderable, the pressure upon the gas remained constant during the experiment: it was the volume which changed. Applying the same method to other gases and to vapours, Gay-Lussac concluded that all gases and vapours (at temperatures sufficiently removed from their points of liquefaction) expanded by heat to the same extent; that, namely, when heated from 0° to 100° C. they expanded in the proportion of 1 : 1·375, or for 1° C. by 0·00375 = $\frac{1}{267}$ of their volume at 0°.

The confidence which these results naturally excited, in consequence of the high reputation of the author, was still further increased by the confirmation which they received at the hands of Dulong and Petit, and also because it was considered probable, on theoretical grounds, that in substances in which cohesive force no longer existed, the expansive action of heat should be independent of chemical composition. Hence, when the Swedish physicist Rudberg announced, as the result of his own more accurate experiments, that the coefficient of expansion found by Gay-Lussac was considerably too high, the statement was at first received with hesitation.

Rudberg determined the value of the coefficient of expansion of air $\left(\frac{1}{a}\right)$ between 0° and 100° C. by two series of experiments. In the first he determined the contraction undergone by a given quantity of air on cooling from 100° to 0° under a nearly constant pressure; in the second, the difference in the elastic force at 0° and 100° of a quantity of air kept at the same volume at the two temperatures. Making t and t' in equations (*c*) and (*d*) respectively = 100 and 0, the results of his experiments may be stated as follows:—The mean of twelve experiments by the first method gave for the coefficient of expansion under constant pressure—

$$\frac{1}{a} = \frac{v - v'}{100v'} = 0{\cdot}003648 = \frac{1}{274};$$

the mean of ten experiments by the second method gave for the coefficient of expansion at constant volume—

$$\frac{1}{a} = \frac{p - p'}{100p'} = 0{\cdot}003646 = \frac{1}{274},$$

a result identical with the preceding.

More recently (1841) the expansion of air and other gases has been again made the subject of elaborate experiments by Regnault (*Relation des Expériences . . . . pour déterminer les principales lois et les données numériques qui entrent dans le calcul des Machines à Vapeur*, Mém. Acad. Roy. des Sciences, xxi. 1–120 (1847); also Ann. Ch. Phys. [3] iv. 5 and v. 52) and by Magnus (Pogg. Ann. lv. 1, and lvii. 177).

Regnault made five series of experiments by methods more or less distinct. His first method was the same as the first method employed by Rudberg. It consisted in heating a cylindrical glass vessel of known capacity, about 2·5 or 3 centimetres wide, and about 11 centimetres long, filled with dry air, to 100°; sealing it hermetically at that temperature; then cooling it to 0°, and observing the quantity of mercury which entered on breaking off the point of the instrument under the surface of that metal. The apparatus employed and the method of experimenting were, in fact, exactly the same as in determining a temperature by means of the air-thermometer in the manner already described (pp. 19 and 20): for it is obvious that the same experiment which, the coefficient of expansion of air being known, serves to determine the temperature at which the air-thermometer is sealed, would, if this temperature were known, serve for the determination of the coefficient of expansion.

The second set of determinations were made by a method only slightly different from the first, the only essential difference in the apparatus being that the tube connected with the air-reservoir was about 40 centimetres (16 inches) long, and that a portion of it, about two inches long and separated from the air-reservoir by about four inches, was wide enough to produce only a very slight capillary depression in a column of mercury. The effect of this modification of the apparatus was that when, after being heated to 100° and sealed at that temperature, the instrument was placed with the tube pointing vertically downwards and with the point dipping into mercury, the mercury rose only as far as the wide part of the tube, on breaking off the point, and did not reach the reservoir at all. Hence the space occupied by the air at zero differed from that which it had occupied at 100°, only by the capacity of that portion of the tube which became filled with mercury on opening the point; and since the diameter of the tube was, with the exception of the wider portion already mentioned, very small, this capacity bore a small proportion to the total capacity of the instrument. The experiment consisted therefore essentially in a determination of the difference of the elastic force of the air at the two temperatures.

Digitized by Google

In the third and fourth sets of experiments, the air-reservoir was made to communicate with a manometer, whereby the pressure upon the enclosed air could be varied at will and accurately measured. The pressures were so regulated that the air was caused to occupy accurately the same volume at 0° and 100°, and the differences of pressure required were determined. The apparatus for the third series of experiments was copied, with some improvements of detail, from that employed by Rudberg in his second series. The apparatus for the fourth series was the same in principle, but its construction was such that the pressure upon the air could be determined with still greater accuracy than was possible with the preceding apparatus.

In the fifth set of experiments, the pressure upon the air remained constant, and the alteration of volume was determined by weighing the quantity of mercury which filled the space into which it expanded.

The mean results of numerous experiments made by each of these processes were as follows:—If p_0 and v_0 represent respectively the pressure and volume of the air at 0°, and p_1 and v_1 its pressure and volume at 100°, the value of $\frac{p_1 v_1}{p_0 v_0}$ was—

By the first series	1·36623
„ second series	1·36633
„ third series	1·36679
„ fourth series	1·36650
„ fifth series	1·36706

In the second, third, and fourth series, the expansion was calculated from the change of elastic force undergone by the same volume of air when its temperature changed between 0° and 100°; in the experiments made by the first method, both pressure and volume changed considerably, so that they gave a mixed result. From the consideration of all the experiments by the first four methods, Regnault adopts for the coefficient of expansion of air, under *constant volume*, for 1 degree centigrade between 0 and 100°, the number

$$0{\cdot}003665 = \frac{1}{272{\cdot}9} = \frac{1}{273} \text{ nearly.}^*$$

This result agrees precisely with that obtained by Magnus.

For the coefficient of expansion of air under *constant pressure*, Regnault adopts the number

0·00367

given by the experiments of the fifth series.

Similar experiments extended to other gases gave the mean results recorded in the following table, in which are also included the results obtained by Magnus:—

Table of Expansion of Gases *between* 0° *and* 100° *at Ordinary Pressures.*

Name of gas.	Value of $\frac{p_1 v_1}{p_0 v_0} = 1 + \frac{100}{a}$.		
	Constant volume.		Constant pressure.
	Regnault.	Magnus.	Regnault.
Hydrogen . . .	1·3667	1·3657	1·3661
Air	1·3665	1·3665	1·3670
Nitrogen . . .	1·3668		
Carbonic oxide . .	1·3667	. .	1·3669
Carbonic anhydride .	1·3688	1·3691	1·3710
Nitrous oxide . .	1·3676	. .	1·3719
Sulphurous anhydride .	1·3845	1·3856	1·3903
Cyanogen . . .	1·3829	. .	1·3877

The foregoing results are all deduced from experiments in which the gases operated upon were subject to pressures differing but little from the ordinary pressure of the atmosphere. In another investigation (*Op. cit.* pp. 96–120) Regnault determined the coefficients of expansion of air and some other gases at pressures considerably different from that of the atmosphere. The following table gives the mean results:

* If the coefficient of expansion of air be taken = 0·0036666 . . . . it may be represented by the vulgar fraction $\frac{11}{3000}$, a number which is very convenient for the purposes of calculation.

The following general conclusions may be drawn from these results:

1°. The coefficients of expansion of air, hydrogen, nitrogen, and carbonic oxide, between 0° and 100°, are sensibly equal.

2°. The coefficients of expansion of the condensable gases, carbonic anhydride, nitrous oxide, sulphurous anhydride, and cyanogen, are slightly greater than the coefficient of expansion of the permanent gases. For the condensable gases also the coefficient of expansion (under constant pressure) slightly exceeds the coefficient of increase of elasticity (the gas being kept at constant volume), a difference which is likewise observed, though in a less degree, in the case of air.

3°. The coefficient for hydrogen is not influenced by a change of pressure from 1 to 3 atmospheres. The coefficients for air, carbonic anhydride, and sulphurous anhydride are greater at high densities and pressures than at low ones.

Notwithstanding the differences in the absolute values of the coefficients of expansion of air at different densities, and of air, hydrogen, and carbonic anhydride, Regnault found by direct experiments (*Op. cit.* pp. 171–190) that the elastic force of air, of any initial pressure at 0° between 400 mm. and 1300 mm., and the elastic force of hydrogen and carbonic anhydride increased according to the same law at all temperatures between 0° and 350° C. Hence gas-thermometers filled with air of any density, or with hydrogen, or carbonic anhydride, would give perfectly similar indications, provided that, in calculating the temperatures, the coefficient proper to each gas were employed. The coefficient of expansion of sulphurous anhydride was found to diminish, relatively to that of air, in proportion as the temperature rose, being 0·0038251 at 98·12° of the air-thermometer, and 0·0037893 at 310·31°.

Hence as a general conclusion: Although no gas appears to follow *absolutely* the law

Digitized by Google

of expansion expressed by the equations (*a*) and (*b*), page 45, the permanent gases follow this law so closely that, in all except the most refined calculations, these formulæ may be taken as strictly applicable to them, the value of a being for all a number sensibly equal to 273.

The following consequences of these equations are of importance in calculating the changes of volume and elastic force of gases corresponding to given changes of temperature: Let v be the volume of a given weight of gas at 0° C., and p its elastic force at the same temperature; let v_1 and p_1 be the volume and elastic force of the same quantity of gas at any other temperature, t_1°; and let v_2 and p_2 be the volume and elastic force corresponding to any third temperature, t_2°: then, the volume at t_1, expressed in terms of the volume at 0°, will be—

$$v_1 = v\frac{p}{p_1}\cdot\frac{a+t_1}{a} = v\frac{p}{p_1}\cdot\left(1+\frac{1}{a}t_1\right),$$

or
$$v_1 = v\frac{p}{p_1}\cdot\frac{273+t_1}{273} = v\frac{p}{p_1}\cdot\left(1+\frac{1}{273}t_1\right) = v\frac{p}{p_1}\cdot\left(1+0{\cdot}003665\,t_1\right);$$

the volume at 0°, in terms of the volume at t_1°, will be—

$$v = v_1\frac{p_1}{p}\cdot\frac{a}{a+t_1} = v_1\frac{p_1}{p}\cdot\frac{1}{1+\frac{1}{a}t_1},$$

or
$$v = v_1\frac{p_1}{p}\cdot\frac{273}{273+t_1} = v_1\frac{p_1}{p}\cdot\frac{1}{1+\frac{1}{273}t_1} = v_1\frac{p_1}{p}\cdot\frac{1}{1+0{\cdot}003665\,t}$$

and the volume at t_2°, in terms of the volume at t_1°, will be—

$$v_2 = v_1\frac{p_1}{p_2}\cdot\frac{a+t_2}{a+t_1} = v_1\frac{p_1}{p_2}\cdot\frac{1+\frac{1}{a}t_2}{1+\frac{1}{a}t_1},$$

or
$$v_2 = v_1\frac{p_1}{p_2}\cdot\frac{273+t_2}{273+t_1} = v_1\frac{p_1}{p_2}\cdot\frac{1+0{\cdot}003665\,t_2}{1+0{\cdot}003665\,t_1}.$$

The elastic force at t_1°, in terms of the elastic force at 0°, will be—

$$p_1 = p\frac{v}{v_1}\cdot\frac{a+t_1}{a} = p\frac{v}{v_1}\cdot\left(1+\frac{1}{a}t_1\right),$$

or
$$p_1 = p\frac{v}{v_1}\cdot\frac{273+t_1}{273} = p\frac{v}{v_1}\cdot\left(1+\frac{1}{273}t_1\right) = p\frac{v}{v_1}\cdot\left(1+0{\cdot}003665\,t_1\right);$$

the elastic force at 0°, in terms of the elastic force at t_1°, will be—

$$p = p_1\frac{v_1}{v}\cdot\frac{a}{a+t_1} = p_1\frac{v_1}{v}\cdot\frac{1}{1+\frac{1}{a}t_1},$$

or
$$p = p_1\frac{v_1}{v}\cdot\frac{273}{273+t_1} = p_1\frac{v_1}{v}\cdot\frac{1}{1+\frac{1}{273}t_1} = p_1\frac{v_1}{v}\cdot\frac{1}{1+0{\cdot}003665\,t_1};$$

and the elastic force at t_2°, in terms of the elastic force at t_1°, will be—

$$p_2 = p_1\frac{v_1}{v_2}\cdot\frac{a+t_2}{a+t_1} = p_1\frac{v_1}{v_2}\cdot\frac{1+\frac{1}{a}t_2}{1+\frac{1}{a}t_1},$$

or
$$p_2 = p_1\frac{v_1}{v_2}\cdot\frac{273+t_2}{273+t_1} = p_1\frac{v_1}{v_2}\cdot\frac{1+0{\cdot}003665\,t_2}{1+0{\cdot}003665\,t_1}.$$

It is very important to bear in mind, with reference to all calculations of this kind, that when the coefficient of expansion of the permanent gases is said to be uniform at all temperatures, and equal to $\frac{1}{273}$, it is not meant that 1 vol. of a gas at any temperature, t_1°, becomes $1\frac{1}{273}$ vol. at the temperature $(t+1)$°; but that 1 vol. at 0° becomes $1\frac{1}{273}$ vol. at 1°, and $1+\frac{t}{273}$ vol. at t°, and that consequently 1 vol. at t° becomes $1+\frac{1}{273+t}$ at $(t+1)$°.

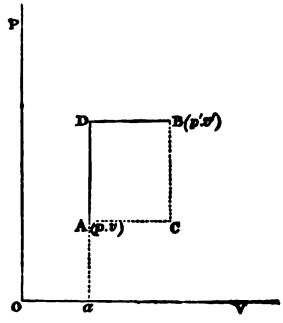
Digitized by Google

The irregularities in the expansion of the more condensable gases, particularly sulphurous anhydride, which are brought to light by Regnault's experiments, are met with to a greater or less extent in the case of all liquefiable gases or vapours, and are more marked in proportion as the gases are examined nearer to their points of liquefaction. The law with regard to the expansion of vapours appears to be, that their coefficients of expansion are considerably greater than $\frac{1}{273}$ at temperatures near to the boiling points of the liquids from which they are formed, and that they continue to diminish as the temperature rises, so as to approach more and more closely to a constant value of nearly $\frac{1}{273}$. Hence, at sufficiently high temperatures, all vapours and liquefiable gases acquire the properties of sensibly perfect gases. The rapidity with which the coefficients of expansion of different vapours approach their limiting values, varies greatly. Some vapours, as that of ether, have a nearly uniform rate of expansion within twenty or thirty degrees of the boiling point of the liquid, whereas others show a sensibly diminishing rate of expansion throughout a much wider interval of temperature: for instance, acetic acid through upwards of 120 degrees, and sulphur-vapour through 400 degrees above the boiling point of sulphur. This property of vapours is of great importance in relation to the experimental determination of their densities. (For further details, see SPECIFIC GRAVITY; also ii. 811.) The fact of a vapour having reached a temperature at which its rate of expansion is the same as that of air, is indicated by its density, compared with that of air at the same temperature and pressure, remaining constant for any further rise of temperature: thus the density of acetic acid vapour (boiling point 118°) was found, by Cahours, to be,

at	125°,	150°,	180°,	200°,	240°,	270°,	310°,	336° C.,
=	3·180,	2·727,	2·438,	2·248,	2·090,	2·088,	2·085,	2·083.

That is to say, it expands more rapidly than air up to about 240°, but above that temperature its expansion is very nearly the same as that of air.

Relation between the Expansion of a perfect Gas and the Quantity of Heat required to produce it.—Equation (*a*) (page 45) may be written—



$$p v = m (1 + \alpha t), \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (e)$$

if we put m for Ja, and α for $\frac{1}{a}$ = coefficient of expansion. Let the volume, v, be expressed in cubic metres, the pressure, p, in kilogrammes per square metre, and the temperature, t, in degrees of the centigrade thermometer. Then, since m is a constant, its value is independent of the variations of v, p, and t, and in order to find it, we may make any suppositions we please with regard to these factors. To determine its value, let p be the normal atmospheric pressure of 0·76 metre referred to 1 square metre, = 10,333 kilogr., let v be one cubic metre, and let t be 0° C. Then we see that m must be the atmospheric pressure on 1 square metre = 10,333 kilogr. = H, and we have—

$$p v = H(1 + \alpha t) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (f)$$

In *fig.* 533 let distances measured parallel to the axis of abscissæ, OV, represent volumes, and distances measured parallel to the axis of ordinates, OP, represent pressures. Then, since the condition of a gas is defined if p and v, two of the three variable quantities upon which it depends, are known, that condition may be represented by the position of a point relatively to the lines OP and OV. Let the point A represent the initial condition (p . v) of a gas: we will consider the quantities of heat which must be imparted to, or withdrawn from, the gas, in order to make it pass through the series of conditions represented by the sides of the rectangle ADBCA, parallel to OP and OV.

Fig. 533.

1. When the gas passes from the state A to the state D, its elastic force increases while its volume, v, remains unaltered; to produce this change, its temperature must be raised from t to the temperature t_1 which is given by the equation $p' v = H(1 + \alpha t_1)$, which, combined with (f), $pv = H(1 + \alpha t)$, gives $(p - p)v = H\alpha(t_1 - t)$. Hence, putting D for the weight of a cubic metre of the gas at 0°, and c for its specific heat when kept at a constant volume, we have for the quantity of heat which must be imparted to the gas to produce the change in question, the expression—

$$q = Dc(t_1 - t);$$

Digitized by Google

but, by the last equation, $t_1 - t = v\frac{p' - p}{Ha}$, therefore—

$$q = \frac{D}{Ha} c\, v\, (p' - p) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (g)$$

2. When the gas passes from the condition D to the condition B, it remains under the constant pressure p', but its volume increases from v to v': its temperature must therefore be still further raised to t', which is given by the formula $p'v' = H(1 + at')$. This, combined with $pv = H(1 + at_1)$, gives $p'(v' - v) = Ha(t' - t_1)$; hence the quantity of heat required will be $q_1 = Dc'(t' - t_1)$, c' denoting the specific heat under constant pressure. Putting for $t' - t_1$ its value deduced from the previous equation, this becomes—

$$q_1 = \frac{D}{Ha} c' p' (v' - v) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (h)$$

3. In passing from the condition B to the condition C, the gas is cooled without change of volume; the corresponding temperature t_2 is therefore given by the formula $pv' = H(1 + at_2)$, which, combined with $p'v' = H(1 + at')$, gives $(p' - p)v' = Ha(t' - t_2)$. The heat that must be withdrawn will therefore be $q' = Dc(t' - t_2)$, or, by substitution—

$$q' = \frac{D}{Ha} c\, v' (p' - p) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (i)$$

4. Lastly, when the gas passes from the condition C to its original condition A, it cools under the constant pressure p, and its temperature again becomes t, defined by the formula $pv = H(1 + at)$, which, combined with $pv' = H(1 + at_2)$, gives $p(v' - v) = Ha(t_2 - t)$. The quantity of heat to be withdrawn, to cause the temperature to fall from t_2 to t, will be $q'_1 = Dc'(t_2 - t)$, which, by substitution, becomes—

$$q'_1 = \frac{D}{Ha} c' p (v' - v) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (k)$$

The general result is that, during the passage of the gas from the state A to the state B, a quantity of heat is expended which (by g and h) is represented by—

$$Q = q + q_1 = \frac{D}{Ha} [c\, v\, (p' - p) + c' p' (v' - v)]; \quad . \quad . \quad . \quad . \quad (l)$$

and that, during the return of the gas from the condition B to the condition A, a quantity of heat is evolved, which (by i and k) is expressed by—

$$Q' = q' + q_1' = \frac{D}{Ha} [c\, v' (p' - p) + c' p (v' - v)]. \quad . \quad . \quad . \quad . \quad (m)$$

Consequently, there is an ultimate expenditure of a quantity of heat equal to—

$$Q - Q' = \frac{D}{Ha} (c' - c) (p' - p) (v' - v),$$

a quantity which is necessarily positive, so long as $p' - p$ and $v' - v$ are positive (that is, so long as any actual increase of pressure and volume takes place), being proportional to the product of these two quantities, and represented by the area of the rectangle ADBCA.

By tracing in the same way the heat expended and evolved in the cycle of changes represented by the passage of the point A about the same rectangle, but in the opposite direction, ACBDA, it would be found that, as a final result, a quantity of heat $= Q - Q'$ would be *evolved* by the process instead of expended. Hence we see that the quantity of heat necessary to change the condition of a gas from A $(p\,.\,v)$ to B $(p'\,.\,v')$, depends not only on the nature of the conditions A and B, but also on the manner in which the passage from one to the other takes place.

If B approaches indefinitely near to A, the quantity of heat, $Q - Q'$, expended or evolved as the point A passes round the rectangular circuit approaches indefinitely to the value 0. That is, in order to cause a gas to pass from the condition A to the condition B, infinitely near to it, the same infinitely small quantity of heat must be expended whether the passage is in the direction ADB, the direction ACB, or that of the diameter of the rectangle, AB. Hence, an element, AB, of any curve may be replaced by its two projections DA and DB parallel to the axes, and changes of condition represented by curve-lines may be considered as made up of rectangular elements parallel to these axes, so that the result derived from the consideration of the rectangular circuit ADBCA may be extended to a closed circuit of any form whatever. (Bourget, Ann. Ch. Phys. [3] lvi. 257; also Daguin's *Traité de Physique*, 2nd ed. ii. 512.—See further the section of this article: Relations of Heat to Mechanical Energy.)

Attention must here be drawn to an important consequence of the relations that we

Digitized by Google

have found to exist between the pressure, volume, and temperature of a gas. The consequence referred to will be most easily deduced from the above equations (*h*) and (*k*), which show that, when a gas expands from the volume v to the volume v', under the constant pressure p, a quantity of heat is absorbed equal to

$$q = \frac{D}{Ha} c' p (v' - v),$$

and that when the gas contracts from the volume v' to the volume v, under the same pressure, an equal quantity of heat is evolved. It is plain, however, from the above equation, that if p, the pressure upon the gas, is nothing, the quantity of heat, q, needed to cause the gas to expand will also be nothing. This condition is actually fulfilled when, instead of having to force up a piston or overcome the pressure of the atmosphere in its expansion, a gas is allowed to expand into a vacuous space; and it has been experimentally proved by Joule that the expansion of a gas, under these circumstances, is not attended with expenditure or absorption of heat. He immersed two copper vessels in water, and removed the air from one and compressed an additional quantity of air into the other, until the pressure amounted to 22 atmospheres: on opening a communication between the two, air rushed from the latter vessel into the exhausted one until the pressure in both was 11 atmospheres. Nevertheless, the water by which they were surrounded indicated no alteration of temperature.

Absolute Zero of Temperature.—It results from the fundamental formula of gaseous expansion,

$$p v = J (a + t),$$

that, if the temperature, t, of a gas were reduced until it became $= -a = -273$, the gas would cease to have any gaseous elasticity—the product of elastic force into volume would be $= 0$. The temperature $-273°$ C. is therefore called the **absolute zero** of temperature, and temperatures reckoned from it are called **absolute temperatures**. These are obviously obtained in any case by adding 273 to the number of degrees by which a temperature is expressed on the centigrade scale; and by employing them in the expression of the laws regulating the relations between temperature and other properties, the resulting expressions are often much simpler than those required when temperatures are expressed according to any ordinary thermometric scale. Thus, for instance, by using τ $(= t + 273)$ to denote the absolute temperature corresponding to the centigrade temperature t, we have for the fundamental formulæ (a) and (b) (page 45) relating to pressure, volume, and temperature, the expressions

$$p v = J \tau \text{ and } \frac{p' v'}{p v} = \frac{\tau'}{\tau},$$

and corresponding simplifications will be found to result in many other cases.

Expansion of Liquids.—The relation between the volume of a given weight of liquid and its temperature follows no simple general law, such as that which, as we have seen, applies, at least approximately, in the case of gases. On the other hand, not only has almost every liquid a coefficient of expansion different from that of any other, but the coefficient of the same liquid varies to an important extent with changes of temperature.

In consequence of the small extent to which the volume of liquid substances is influenced by external pressure (ELASTICITY, ii. 370), it may, in all ordinary cases, be considered as a function of their temperature alone, instead of as a function of temperature and pressure combined, as with gases. It results also from the cohesion of liquids, which causes them always to have a definite limiting surface, that their volumes can be determined by observations of a more direct kind than those which can be made on gaseous bodies. Hence, an obvious method of determining the expansion of a liquid, is to observe how many divisions of a vessel graduated into parts of equal capacity, are filled by the same weight of it at various temperatures. Such a method, however, would only be exact if the capacity of the containing vessel were known, not merely at some one temperature, but at each temperature at which an observation of the liquid was made. Thus, it would be inaccurate to conclude that the expansion of a liquid between 0° and 100° amounted to 1 per cent., because the same quantity which filled 100 divisions at the former temperature occupied 101 divisions at the latter; for it is impossible to raise the temperature of a liquid, without at the same time raising the temperature, and so altering the capacity, of the vessel in which it is contained. It is therefore necessary to distinguish between the *apparent* expansion of liquids, or that which would result from observations made in the manner that has been described, without taking account of the changes of capacity of the containing vessel, and their *real* or *absolute* expansion, which is the apparent expansion corrected for the simultaneous expansion of the vessel. Of course, in measuring the changes of volume of gaseous bodies, the expansion of the containing vessel requires to be similarly taken

Digitized by Google

into account, but in this case it is of much less relative consequence than it is in the case of liquids: thus, for example, the apparent expansion of air in a glass vessel would only differ from its real expansion about in the proportion of 140 : 141; whereas, in the case of mercury, the difference would amount to one seventh of the total effect to be observed.

Relation between the Absolute and Apparent Expansion of Liquids.—From what has been already said, it will be evident that the apparent expansion of a liquid is equal to its absolute expansion for the same interval of temperature diminished by the corresponding expansion of the containing vessel. That is, if Δ be the coefficient of absolute expansion of a liquid, and δ its coefficient of apparent expansion, the relation between these two quantities will be the following:—Let V be the volume of the liquid, and consequently of that portion of the vessel which it fills, at 0°; and let V' be the capacity, *estimated at* 0°, of so much of the vessel as it fills when its temperature has been raised 1°. Then the real volume of the liquid at the latter temperature will be $V(1 + \Delta)$, and the real volume of the portion of the vessel occupied by it will be $V'(1 + \kappa)$ (putting κ for the coefficient of cubical expansion of the material of the vessel): hence we have—

$$V'(1 + \kappa) = V(1 + \Delta),$$

or

$$\frac{V' - V}{V} = \frac{\Delta - \kappa}{1 + \kappa};$$

but $V' - V$ is the apparent increase of volume of the liquid, for a rise of temperature of one degree; $\frac{V' - V}{V}$ is therefore its coefficient of apparent expansion $= \delta$. Accordingly—

$$\delta = \frac{\Delta - \kappa}{1 + \kappa}, \text{ or } \Delta = \delta + \kappa + \delta\kappa;$$

but as δ and κ are always small fractions, we may disregard their product, $\delta\kappa$, and put $\Delta = \delta + \kappa$: that is, the *coefficient of absolute expansion of a liquid is equal to its coefficient of apparent expansion in a vessel of any material, increased by the coefficient of cubical expansion of the material of which the vessel is made.*

By far the most accurate method of measuring the capacity of a vessel, and of finding the relative values of divisions which may be marked upon it, is to determine the weight of mercury which fills it up to the zero point of the scale, and also the weight which corresponds to the interval between any two divisions. But since both the capacity of the vessel and the specific gravity of mercury vary with variations of temperature, the different weights of mercury which fill the vessel at different temperatures do not at once enable its relative capacities at these temperatures to be calculated; for this it is necessary that the absolute expansion of mercury should be previously known. Hence the absolute expansion of mercury (which, on account of its inalterability and its property of not wetting glass, is better adapted for measuring purposes than any other liquid) is a necessary preliminary datum for the determination of the absolute expansion of liquids in general.

Determination of the Absolute Expansion of Mercury.—Enough has already been said to make it evident that, in order to obtain a trustworthy determination of this constant, some method must be devised whose results are wholly unaffected by changes in the capacity of the vessel in which the mercury is contained. A satisfactory solution of this apparently very difficult problem was first given by Dulong and Petit (Ann. Ch. Phys. [2] vii. 124 (1817); Daguin's *Traité de Physique*, 2nd ed. ii. 187; see also Regnault, *Relation des Expériences, &c.*, pp. 277–280. Paris, 1847). Their method consisted in measuring the heights of columns of mercury at different temperatures, which produced equilibrium with another column of the same liquid of constant height, and kept always at 0°.

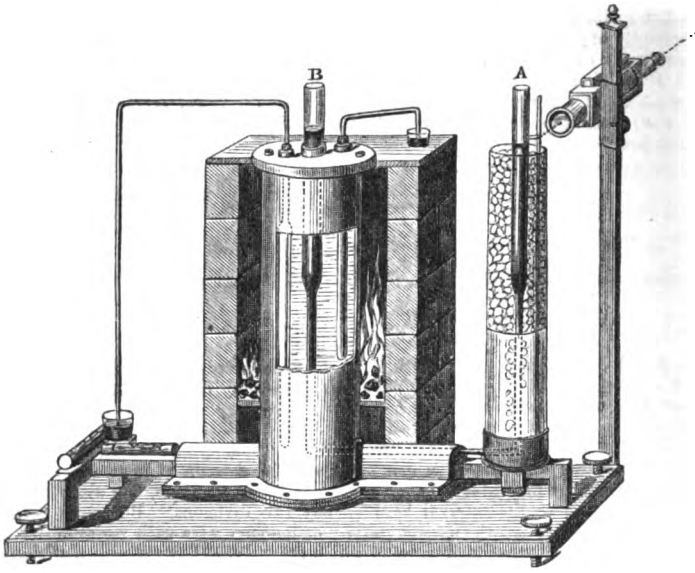
If h denotes the height of the column at 0°, d the density of mercury at this same temperature, h' the height of the column at t°, which produces equilibrium with the first, and d' the density of mercury at the temperature t, we have—

$$\frac{h'}{h} = \frac{d}{d'}.$$

Representing by v and v' the volumes of the same weight of mercury at 0° and at t°, we get—

$$\frac{d}{d'} = \frac{v'}{v}, \text{ and consequently } \frac{v'}{v} = \frac{h'}{h}.$$

The mean coefficient of expansion between 0° and t° is therefore—



$$\delta_t = \frac{v' - v}{vt} = \frac{h' - h}{ht},$$

Digitized by Google

and its determination requires only that the difference of height of the two columns, and the absolute height of the column at zero, should be accurately measured.

The apparatus employed by Dulong and Petit for the purpose of putting this method into practice is represented in *fig.* 534. It consisted of a kind of inverted glass syphon, the two vertical branches of which (A and B) were about 0·55 metre long, and communicated below by a horizontal tube of very small diameter. The branch A was surrounded by a cylinder of tinned iron which was kept full of ice; the other branch, B, occupied the middle of a cylindrical copper vessel filled with oil and built into a furnace.

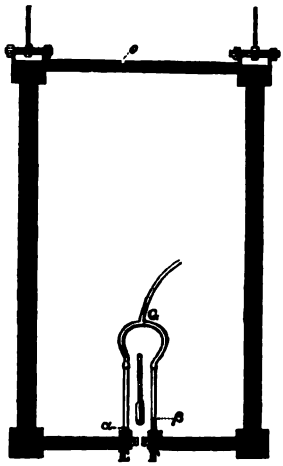
Fig. 534.

(In the figure, the front wall of the furnace, as well as a part of the cylinders surrounding each branch of the syphon, is represented as having been removed.) The quantity of mercury in the apparatus was so adjusted that the meniscus in the tube B was a little above the cover of the oil-bath, and the difference in the height of the two columns was measured by a cathetometer (an instrument devised by Dulong and Petit and first used in this investigation). The temperature of the oil-bath was indicated by an air-thermometer and a mercurial weight-thermometer (pp. 18, 19), the reservoirs of which were of the same length as the mercury-column in the tube B, and were placed near to and parallel with it.

The following table gives the general results of a great number of determinations made with this apparatus:

Absolute Expansion of Mercury (Dulong and Petit).

Temperatures by the air-thermometer.	Mean coefficient of Expansion counted from 0°.		
	Maximum values.	Minimum values.	Mean values.
100° C. . .	$\frac{1}{5547}$	$\frac{1}{5552}$	$\frac{1}{5550}$ = 0·00018018
200° . . .	$\frac{1}{5419}$	$\frac{1}{5431}$	$\frac{1}{5425}$ = ·00018433
300° . . .	$\frac{1}{5288}$	$\frac{1}{5309}$	$\frac{1}{5300}$ = ·00018868



Notwithstanding the great approach to accuracy which was undoubtedly made in these experiments, the results were still affected by sources of error which, in the determination of a physical constant of such primary importance as the one in question cannot be considered as immaterial. The chief of these are: the uncertainty of the determinations of the temperature of the heated column, arising (1) from the employment of the old (and inaccurate) coefficient for the expansion of air, namely 0·0037

Digitized by Google

in reducing the indications of the air-thermometer; (2) the cooling effect of the external air upon the portion of the heated column which rose above the cover of the oil-bath; (3) the want of uniformity in the temperature of the oil-bath at different depths; and the comparative shortness of the two mercury-columns, whereby a very small absolute error in the measurement of h and h' comes to have a considerable effect on the value of the fraction $\frac{h' - h}{ht} = \delta$.

In order to obtain results which should be, as far as possible, free from the errors thus arising, Regnault (*Relation des Expériences, &c.*, pp. 271–328. Paris, 1847) repeated the determination of the absolute expansion of mercury, by a method similar in principle to that of Dulong and Petit, but somewhat different in execution. The arrangement of his apparatus will be intelligible from *fig.* 535. AB and CD are two iron tubes, 1·5 metre long and 10 mm. in internal diameter (in the figure the diameter is greatly exaggerated in proportion to the length), connected above by the horizontal iron tube AC, of 2·5 mm. (0·1 inch) internal diameter, and respectively communicating below with the horizontal tubes BE and DF, likewise of 2·5 mm. diameter, which in their turn carry the vertical glass tubes EG and FG. The apparatus having been adjusted so that the tubes AB and CD are exactly vertical, and the tubes AC, BE, and DF exactly horizontal, mercury is poured into it through one of the short tubes, open at both ends, by which both AB and CD are surmounted, and in proportion as the liquid rises in the glass tubes EG and FG, air is compressed into a copper receiver communicating with them by the leaden pipe G, so as to keep the level of the mercury near the bottom of the glass tubes. The addition of mercury is continued until it begins to run out at a hole, O, bored in the upper side of the tube AC. The vertical tube AB is placed in the centre of an oil-bath; CD is surrounded by a constant current of cold water.

Fig. 535.

On heating the tube AB, the density of the mercury contained in it was of course diminished, and consequently equilibrium of pressure in the tubes EG and FG could only be maintained by the sinking of the mercury-column in the former. The elastic force of the compressed air in the receiver was therefore balanced—on the one hand, by the pressure of the heated column of mercury of the height AB, $= H$, diminished by that of the column in E, $= h$; on the other hand, by the pressure of the cold column CD, $= H'$, diminished by that of the column in F, $= h'$. The temperature of the column AB was indicated by an air-thermometer, that of CD by three mercurial thermometers in the water-vessel which surrounded it, and that of the mercury in E and F by a thermometer placed between them as shown in the figure. When the necessary corrections for the differences of temperature of the several mercury-columns had been applied, the formula for the absolute expansion became—

$$\frac{(H' - h') - (H - h)}{(H' - h')t} = \delta.$$

But since the required corrections involved the knowledge of the very coefficient sought, the calculation could only be made by the method of successive approximations: that is, Dulong and Petit's coefficient was first assumed in order to calculate an approximate result; then the number so obtained was substituted for the old coefficient, and so a still more accurate result was arrived at.

In another series of experiments, the tubes AB and CD were connected at the bottom by a continuous horizontal tube, and the tube AC was cut across, vertical glass tubes being inserted into the two halves, wherein the different heights attained by the mercury-columns could be observed. In this state, the apparatus was merely a modified form of that employed by Dulong and Petit.

The results ultimately arrived at are given in the following table, the temperatures in the first column of which are those measured by the air-thermometer.

The numbers in the last column of this table represent the amounts by which a unit volume of mercury expands for a rise of temperature of one degree centigrade at various temperatures between 0° and 350°. Thus, 100,000,000 cubic millimetres of mercury, measured at 0°, occupy 100,017,905 cubic millimetres at 1°; 100,000,000 cubic milli-

350	1·065743	0·00018784	0·00019666

metres, measured at 300°, become 100,019,413 cubic millimetres at 301°. Accordingly, the true coefficient of expansion increases as the temperature rises. The third column contains the quotients obtained by dividing the difference between the volume (V_t) of mercury at $t°$ and the volume of the same weight at 0° ($V_0 = 1$) by the number of degrees of temperature ($= t$), that is to say, the mean coefficient of expansion between 0° and $t°$, $\frac{V_t - 1}{t}$. Between 0° and 100°, the mean coefficients vary so little that the real expansion of mercury, and much more therefore its smaller apparent expansion in glass, may be taken as proportional to the temperature measured by the air-thermometer. A careful comparison of an air-thermometer and a mercurial thermometer, upon which the points 0° and 100° had been determined under the same circumstances, and which therefore necessarily agreed at these temperatures, showed the following differences between the indications of the two instruments:

Temperatures by air-thermometer—

−36° 0° +100° 129·9° 148·7° 197·0° 245° 292·7° 340°;

Temperatures by mercurial thermometer—

−36° 0° +100° 130° 150° 200° 250° 300° 350°.

From Regnault's table it results that, if the real expansion of mercury be taken as the measure of temperature, the following readings of the air- and mercurial thermometers will indicate the same temperatures—

* In Regnault's original paper, the true coefficient of expansion at 100° is given, doubtless in consequence of a misprint, as 0·00018305, and the same number is repeated in various other places: *e.g.* Handwörterb. der Chemie, 2nd ed. ii. [1], 867, article *Ausdehnung*; also Daguin's *Traité de Physique*, ii. 193. Paris, 1861.

Digitized by Google

Air-thermometer—

0° 50° 100° 130° 150° 200° 250° 300° 350°;

Mercurial thermometer—

0° 49·6° 100° 130·5° 151° 202·8° 255·2° 308·3° 362·2°.

By a series of observations of the heights of two mercurial barometers, one of which was kept at a temperature near 0° C., while the other was heated to a higher temperature, Militzer (Pogg. Ann. lxxx. 55) obtained for the mean coefficient of absolute expansion of mercury between 0° and 100°, the number

$$0{\cdot}00017405 \pm 0{\cdot}00000082 = \frac{1}{5745{\cdot}4}\left(1 \pm \frac{1}{212}\right),$$

which differs considerably from Regnault's result, and is probably less accurate.

Apparent Expansion of Mercury, and determination of the Cubical Expansion of Glass vessels.—By help of the foregoing table of the absolute expansion of mercury, the cubical expansion of glass vessels may be determined. For this purpose the neck of the vessel is drawn out to a capillary point; it is filled with mercury, care being taken to exclude all moisture or air; exposed successively to the temperatures 0° and 100°, and weighed with the quantity of mercury which fills it at each of these temperatures. Let

the weight of the empty glass vessel be . . . . . = w,
the weight of the vessel filled with mercury at 0° . . . . . = W,
the weight of the vessel filled with mercury at 100° . . . . . = W',

let Δ be the absolute expansion of mercury, and κ the cubical expansion of glass between 0° and 100°; then we have

$$\frac{W - w}{W' - w} = \frac{1 + \Delta}{1 + \kappa}, \text{ and therefore } \kappa = \frac{W' - w}{W - w}(1 + \Delta) - 1.$$

When once the cubical expansion of a glass vessel is known, the absolute expansion of any liquid can be deduced, in the manner already explained (p. 53), from its apparent expansion as observed in this vessel. Hence a problem of frequent occurrence is to determine the expansion of the glass of a vessel shaped like a thermometer, and provided with a divided stem, for which the relative capacities of the bulb and of one division of the stem have been previously determined. In such a case, it is only necessary to fill the apparatus to some particular point of the scale with well-boiled mercury, and to observe the apparent volumes of the mercury, v and v', at 0° and 100°, expressed in divisions of the scale: the expansion of the glass can then be calculated. For (p. 53) the apparent volume of the mercury at 100° is equal to its volume at 0° increased by the amount of its absolute expansion between 0° and 100°; that is:—

$$v'(1 + \kappa) = v(1 + \Delta), \text{ or } \kappa = \frac{v}{v'}(1 + \Delta) - 1.$$

The apparent expansion of mercury in glass varies with the kind of glass employed, but may be taken on an average = 0·0001545 for each degree centigrade. This value may be used, for instance, without hesitation in calculating the corrected length of the portion of the thread of mercury in a thermometer which is not exposed to the temperature that is to be measured. (See below, *Determination of Boiling Points.*) Between 0° and 100° the apparent volume of mercury in glass increases in the proportion of 1 : 1·01545, while the real volume increases in the proportion of 1 : 1·01815; hence the cubical expansion of glass is

$$\kappa = \frac{1{\cdot}01815}{1{\cdot}01545} - 1 = 0{\cdot}002663.$$

Another case in which the absolute expansion of mercury requires to be taken into account, is in reducing barometric observations to 0° C. (Barometer, i. 512, 513.)

Expansion of other Liquids.—The absolute expansion of any liquid can now be ascertained by filling with it a small glass bottle, whose cubical expansion has been previously ascertained in the manner already described, and weighing the bottle with the quantity of liquid which fills it at different temperatures. But a more rapid method, and therefore one more frequently adopted, is to observe the apparent expansion of the liquid in a *dilatometer*, an instrument shaped just like a common mercurial-thermometer, and then to correct these observations for the previously known cubical expansion of the glass. In this way very numerous determinations have been made by Isidore Pierre (Ann. Ch. Phys. [3] xv. 325; xix. 193; xx. 5; xxi. 336; xxxi. 118; xxxiii. 199) and by Hermann Kopp (Pogg. Ann. lxxii. 1 and 223; Ann. Ch. Pharm. xciv. 257; xcv. 307; xcvi. 153 and 303; c. 19). The principal results of these investigations are given below.

The numbers in the second column of the above table, compared with that representing the volume of the same quantity of water at 0°, give the following four interpolation-formulæ—

Between 0° and 25° C.

$$V = 1 - 0{\cdot}000061045\,t + 0{\cdot}0000077183\,t^2 - 0{\cdot}00000003734\,t^3.$$

Between 25° and 50°.

$$V = 1 - 0{\cdot}000065415\,t + 0{\cdot}0000077585\,t^2 - 0{\cdot}000000035408\,t^3.$$

Between 50° and 75°.

$$V = 1 - 0{\cdot}00005916\,t + 0{\cdot}0000031849\,t^2 + 0{\cdot}0000000072848\,t^3.$$

Between 75° and 100°.

$$V = 1 - 0{\cdot}00008645\,t + 0{\cdot}0000031892\,t^2 + 0{\cdot}0000000024487\,t^3.$$

It will be seen that, between 0° and a temperature of about + 4°, water presents the exceedingly rare phenomenon of a substance which contracts when heated and expands

Digitized by Google

hen cooled, so that at about 4° it is more dense than at any other temperature. ccording to the first of the above formulæ, the exact temperature at which water ossesses its maximum density would be 4·08°. The results of other experimenters ıdicate in general very nearly the same temperature for this point. For example, Ilällström fixed it at 4·1°, Despretz at 4°, Playfair and Joule at 3·95°, Hagen at 3·87°, rankenheim at 3·86°, Plücker and Geissler at 3·8° (nearly), C. v. Neumann at 3·68°. lthough the melting point of ice (0° C.) is also the point at which water freezes under rdinary circumstances, it may by special precautions be cooled much lower without ecoming solid (p. 74). It is then found that the expansion which takes place when ater is cooled from 4° to 0°, continues as the temperature sinks below the latter tem- erature. This is shown in the following table by Despretz (Daguin's *Traité de Phy- ique*, ii. 205. Paris, 1861), which gives the volumes and densities of water for each legree from − 9° to + 4°, compared with its volume and density at 4° as unity. The omplete table, which extends from − 9° to 100°, agrees in general very closely with hat already given by Kopp; it is therefore not necessary to reproduce it here entire: he portion given corresponds to the last two columns of Kopp's table.

Expansion of Water between − 9° *and* + 4°. (Despretz.)

Tempera- tures.	Volumes.	Densities.	Tempera- tures.	Volumes.	Densities.
− 9°	1·0016314	0·998371	− 2°	1·0003077	0·999692
− 8	1·0013734	0·998628	− 1	1·0002138	0·999786
− 7	1·0011354	0·998865	0	1·0001269	0·999873
− 6	1·0009184	0·999082	+ 1	1·0000730	0·999927
− 5	1·0006987	0·999202	2	1·0000331	0·999966
− 4	1·0005619	0·999437	3	1·0000083	0·999999
− 3	1·0004222	0·996577	4	1·0000000	1·000000

Frankenheim (Jahresber. üb. Chemie, u. s. w., 1852, 51) calculated from Pierre's observations the following empirical formulæ, to express the volume of water at $t°$, compared with its volume at 0° taken as unity:

Between − 13° and 0°.

$$1 - 0{\cdot}00009417\ t + 0{\cdot}000001449\ t^2 - 0{\cdot}0000005985\ t^3.$$

It is not necessary to give the other six similar formulæ which he calculated for other intervals of temperature up to + 98°, nor to reproduce any part of the table which he calculated by means of them, except the following numbers referring to temperatures below 0°:

Temperatures	− 15°	− 10°	− 5°	0°
Volumes .	1·0037684	1·0016851	1·0005819	1·0000000.

Tables of the expansion of water between 0° and 100° have also been constructed by Hagen (see Jahresber. üb. Chemie, u. s. w., 1856, 50), Kremers (*ibid.* 1861, 62), and others.

Kopp's table further shows that water expands more and more rapidly as the temperature rises. This property likewise is found to remain the same when, by increasing the pressure upon it, water is kept liquid at temperatures above 100°. Thus, for example, by observing under the microscope the apparent expansion of water in thermometer-tubes, Sorby (Phil. Mag. [4] xviii. 81) obtained results from which he calculated the following formula for its expansion between 0° and 200°:

$$V = 0{\cdot}9977 + 0{\cdot}000123\ t + 0{\cdot}00000330\ t^2,$$

which accords closely with the formula which he calculated for the same interval of temperature from Kopp's experiments, namely,

$$V = 0{\cdot}997696 + 0{\cdot}0001101\ t + 0{\cdot}00000343\ t^2.$$

Mendelejeff also (Zeitschr. Chem. Pharm. 1861, 33; Ann. Ch. Pharm. cxix. 1) investigated the expansion of water above 100° with the following results:—

Temperatures.	Densities. (Density of water at 4° = 1.)	Volumes. (Volume of water at 0° = 1.)	Volumes calculated by Kopp's formula.
99·8°	0·95903	1·0426	1·0429
131·0	0·93079	1·0722	1·0716
156·8	0·90770	1·1016	1·1014

The presence of saline substances in solution in water renders its rate of more uniform, both below and above 100°. [For determinations of the rate sion of aqueous solutions, see Kremers (Pogg. Ann. c. 394; Jahresber. üb u. s. w., 1857 [1] 44: chlorides of potassium, sodium, lithium, and barium.— Pogg. Ann. cv. 360; Jahresber. 1858, 41: chlorides of calcium, cadmium, s zinc, magnesium; bromides of potassium, sodium, lithium, barium, strontium.— Pogg. Ann. cviii. 115; Jahresber. 1859, 48: bromides of strontium, calcium sium, zinc, cadmium; iodides of potassium and sodium; hydrochloric acid.— Pogg. Ann. cxi. 60; Jahresber. 1860, 45: iodides of lithium, barium, stront cium, magnesium, zinc, cadmium.—Further, Pogg. Ann. cxiv. 41; Jahresber. 1 nitrates and sulphates of potassium, sodium, lithium; aqueous nitric and s acids), Gerlach (Jahresber. 1859, 42–48: chlorides of potassium, sodium, ammonium, magnesium, calcium, barium, aluminium; sulphates of potass sodium; carbonates of potassium and sodium; tartaric acid, citric acid, can and Sorby (*loc. cit.*: chlorides of potassium and sodium, sulphate of sodium).

The temperature of maximum density of aqueous solutions is lower than that water. In fact, with solutions of many substances, this temperature lies lower ordinary freezing-point of the solution, and is in general (as well as the freezin lower the larger the proportion of saline matter contained in the solution.

In the tables which follow, Kopp has collected together the results of his own a Pierre's determinations of the expansion of nearly ninety other liquids, chiefly organ In each table, the several substances are arranged in the order of their boiling-poin beginning with the lowest. Except where the contrary is stated, the volume of ea liquid at 0° C. is taken as the unit, with which its volume at higher temperatures compared.

Table A (Ann. Ch. Pharm. c. 21) gives the expansion of seven nitrogenous co pounds from the determinations of Kopp and Pierre.

Digitized by Google

Table B (*ibid.* xcvi. 163) gives the expansion of forty-two liquids, containing no other elements than carbon, hydrogen, and oxygen, according to the experiments of H. Kopp:—Table C (*ibid.* xcvi. 304) gives the expansion of thirty-eight compounds containing sulphur, iodine, bromine, and chlorine, according to the experiments of Kopp and Pierre.

From the inspection of these tables it will be seen that, as a general, though not universal, rule, those substances expand most rapidly at ordinary temperatures whose boiling-points are lowest; that isomeric compounds having the same boiling-point, expand at the same or very nearly the same rate (*e. g.* formate of ethyl and acetate of methyl, $C^3H^6O^2$; propionate of ethyl and butyrate of methyl, $C^5H^{10}O^2$; butyrate of ethyl and valerate of methyl, $C^6H^{12}O^2$); that the rate of expansion of each liquid increases as the temperature rises. This last fact becomes still more apparent on comparing the coefficients of expansion at different temperatures (for a table of the true and mean coefficients of expansion of the liquids examined by Pierre, see Gmelin's *Handbook*, i. 226), and a consequence of it is that, when the volumes of different liquids are compared at the same number of degrees below their several boiling-points, the volume of each liquid at its boiling-point being taken as unity, the alterations corresponding to equal intervals of temperature are found to be often much more uniform than when the comparison is made (as in the tables which follow) for the same absolute temperatures. (Tables of Pierre's results, calculated for equal distances from the boiling-points, are given in Gmelin's *Handbook*, i. 227–230.)

Observations of the expansion of liquids by the methods already described are limited to temperatures below the ordinary boiling-points, but by special methods such observations can be extended to higher temperatures, and it is then found that the increasing rate of expansion continues up to the highest points at which determinations can be made, so that, under such circumstances, liquids may expand as rapidly as

[a] The volumes given by Drion are the *apparent* volumes, uncorrected for the expansion of the glass: the corrected, or true, volumes would be a little greater.

Digitized by Google

gases, or even more rapidly, for equal increments of temperature. Determinations of the expansion of water above 100°, by Mendelejeff, have already been given (p. 59); the preceding table (p. 66) contains the results of the observations of Drion (Ann. Ch. Phys. [3] lvi. 5), Andréeff (*ibid.* lvi. 317), and Mendelejeff (*loc. cit.*) on some other liquids at temperatures above their usual boiling points. To serve as a standard of comparison, the expansion of air is given in the last column of the table.

Expansion of Solids.—In speaking of the expansion of solid bodies, it is needful to distinguish between *linear* expansion, or the increase in length of a linear unit; *superficial* expansion, or the increase in the area of a unit of surface; and *cubical* expansion, or the increase in bulk of a unit of volume. If a solid body, whose length is A linear units, expands, when heated from 0° C. to 1°, so as to measure $A + a$ at the higher temperature, a portion of its surface containing A^2 superficial units at the lower temperature will become $(A + a)^2$ when expanded, and, at the same time, the volume A^3 will become $(A + a)^3$. We have therefore for the increase in length, or

linear expansion, $A + a - A = a$; for the
superficial expansion, $(A + a)^2 - A^2 = 2Aa + a^2$; for the
cubical expansion, $(A + a)^3 - A^3 = 3A^2a + 3Aa^2 + a^3$.

But since a is always a very small fraction of A, a^2 is also a very small fraction of a; hence the second and third terms of these expressions may be omitted. Accordingly, the expansion of A linear units may be taken as a, the expansion of A^2 superficial units as $2Aa$, and the expansion of A^3 cubical units as $3A^2a$. The *coefficients* of linear, superficial, and cubical expansion, or the expansion of one unit of each kind, will therefore be respectively

$$\frac{a}{A}, \quad \frac{2Aa}{A^2} = 2\,\frac{a}{A}, \quad \text{and} \quad \frac{3A^2a}{A^3} = 3\,\frac{a}{A};$$

that is to say, the coefficient of superficial expansion is *twice* as great, and the coefficient of cubical expansion *three times* as great as the coefficient of linear expansion.

When a hollow vessel is heated, its capacity increases to exactly the same extent as it would do if filled with the substance of which its sides are composed; that is, its expansion is the same as the cubical expansion of a solid mass of the same material and dimensions. If κ be the coefficient of cubical expansion of any kind of glass for a rise of temperature of 1° C., a vessel made of this glass and having the capacity V_0 at 0°, would have at $t°$ the capacity $V_1 = V_0 (1 + \kappa t)$. Similar considerations are applicable in the case of a glass vessel which is divided into parts of equal capacity by a scale etched upon the side, when the space comprised between two consecutive divisions at 0° is taken as the unit of capacity. The apparent volume V_1, read off at $t°$, would then correspond to the real volume $V_0 (1 + \kappa t)$ referred to the unit adopted.

Determinations of Linear Expansion.—The linear expansion has been measured for the greater number of such substances as can be obtained in the form of rods or bars of considerable length. For the purpose of such measurements, one end of the bar is fixed immovably, and its length is measured, by means of micrometric apparatus attached to the other end, at two known temperatures, such as 0° and 100° C., which can be maintained constant sufficiently long to make it certain that they have been attained by the bar throughout its whole mass. The following table of linear expansions between 0° and 100° C. is from Ure's *Dictionary of Chemistry*, ed. 1836, pp. 271, 272.

The last two measurements by an air-thermometer.

Messrs. Calvert, Johnson, and Lowe have determined the linear expansion of a considerable number of metals and alloys by a modification of the method above described, for the details of which we must refer to the original paper published in the *Mechanics' Magazine*.

The following are the linear expansions of simple metals between 0° and 100° C. thus determined:—

Cadmium (pure)	0·00332
Lead (pure)	0·00301
Tin (pure)	0·00273
Aluminium (commercial)	0·00222
Zinc, forged (pure)	0·00220
Silver (pure)	0·00199
Gold (pure)	0·00138
Bismuth (pure)	0·00133
Wrought iron	0·00119
Cast iron	0·00112
Steel (soft)	0·00103
Antimony (pure)	0·00098
Platinum (commercial)	0 00068

From the preceding table it will be seen that the coefficients of expansion of the metals vary with their physical condition, being different for the same metal according as it has been cast, hammered and rolled, hardened, or annealed. As a general rule, those operations which increase the density, appear also to increase the rate of expansion by heat. But even for substances in apparently the same condition, different observers have found very unequal amounts of expansion; this may arise, in the case of compound substances, such as glass, brass, or steel, from a want of uniformity in chemical composition, and in simple bodies from slight differences of physical state. Hence, in all cases where great accuracy is required in the determination of the linear expansion, as in rods employed for pendulum observations, or for the measurement of the base-lines of surveys, it is impossible to rely upon the results of previous determinations of the expansion of the material in question; but the linear expansion of each individual rod must be determined by a special experiment: this was done, for instance, by De Borda, with each of the four platinum measuring rods (each two toises, or twelve French feet long), which were employed in the measurement of the arc of meridian, from which the length of the metre was deduced.

Copper rods were laid upon the platinum rods, and both were firmly fixed together at one end; the copper rods carried a divided scale at the other end, which indicated directly the twenty-thousandth part of their length, while by means of a vernier attached to the corresponding end of the platinum rods, tenths of these divisions, or about the one-hundredth part of a French line, could be read off. In this way, the difference in the expansion of two rods of the same length but different materials can be determined with great accuracy, and if the coefficient of expansion for the material of one rod is known, the coefficient of that of the other can be calculated.

If both rods have the same length, L, at 0°, and at $t°$ one has the length $L' = L(1 + \alpha t)$, the other the length $L'' = L(1 + \alpha' t)$, we have $L' - L'' = L t(\alpha - \alpha')$. But $L' - L''$ is the observed difference of length at the temperature $t°$; and hence if α is known, α' is easily calculated. In this way, Dulong and Petit deduced the linear expansion of copper from that of platinum.

If, on the other hand, the expansion of the material of two rods thus united is known, and can be taken as proportional, within certain limits of temperature, to the indications of the mercurial thermometer, the combination of the two rods may be employed as a metallic thermometer. The measurement of temperatures in this way is specially valuable in the case of standard measures of length, which can thus be made to indicate their own temperature. If, for instance, the two rods have the same length at 0°, and differ at 100° by the amount D, and at $t°$ by the amount d, the temperature is given by the equation $t = \frac{d}{D}\,100$.

The unequal expansion of different metals has been taken advantage of for the co struction of thermometers of another kind. If two straight strips of different meta are fastened together throughout their whole length, any variation of temperature mu cause the compound strip to bend, so that the least expanded metal will be on the co cave side, and the most expanded metal on the convex side of the curve. Breguet' thermometer, constructed upon this principle, is made from a compound plate of platinum gold, and silver, soldered together, the gold in the middle. This is rolled out very thi and cut into very narrow strips, which are coiled round into spirals. The thermomete consists of such a spiral suspended by one end from a support, and carrying a needl which swings round a divided circle at the other.

Supposing the silver to be inside of the spiral, any rise of temperature will be ind cated by the untwisting of the spiral, and a fall of temperature by its twisting mo tightly. The small mass of this instrument, and the low specific heat of the materia composing it, cause it to indicate changes of temperature very rapidly, and to be affecte by very small quantities of heat.

Determinations of Cubical Expansion.—When the coefficient of linear expansion a substance is known, its coefficient of cubical expansion is obtained by multiplyin the linear coefficient by 3, as already explained (p. 67). The cubical expansion ca also be ascertained by direct measurement. The following method was employe by Dulong and Petit for this purpose: Into a glass tube, 18 millimetres wide, decimetres long, and closed at one end, they introduced a rod, previously weighed. a metal not attacked by mercury. Let W be its weight. The tube was then draw out at the open end and bent as in *fig.* 536, after which it was filled with pure me cury, and boil out to remo every trace of a exactly as in filli a mercurial the mometer. In t state the appar tus was placed h rizontally, a surrounded wi

Fig. 536.

melting ice, the point dipping below the surface of mercury contained in a sm capsule. It was thus filled with mercury at 0°. The capsule was next emptie replaced under the point, and the apparatus allowed again to assume the temperatu of the atmosphere. Then, by weighing together the tube and capsule, and deducti from the gross weight their weight before the introduction of the mercury, they o tained the weight, W, of the mercury which exactly filled at 0° so much of the capaci of the tube as was not occupied by the metal rod. The experiment was completed heating the instrument in an oil-bath to a high temperature, t, and weighing t quantity of mercury which escaped from the point, as in the determination of a te perature by means of the weight-thermometer (p. 18).

If D_0 and D_0' represent the densities at 0° of mercury and of the metal; Δ, $\varkappa$, and the coefficients of cubical expansion of mercury, of the metal, and of glass respectivel their volumes at 0° will be represented by

$$\frac{W}{D_0}, \quad \frac{W'}{D_0}, \quad \text{and} \quad \left(\frac{W}{D_0} + \frac{W'}{D_0'}\right);$$

and if w is the weight of mercury which escapes from the tube between 0° and $t°$, t weight of mercury remaining in the tube at the latter temperature will be $W-$ Then putting the volume of this weight of mercury at the temperature t, together wi that of the metal rod at the same temperature, equal to the capacity of the tube whi contains them, we have

$$\frac{W-w}{D_0}(1+\Delta t) + \frac{W'}{D_0'}(1+\varkappa t) = \left(\frac{W}{D_0} + \frac{W'}{D_0'}\right)(1+\kappa t);$$

whence

$$\varkappa = \frac{D_0'}{W'}\left(\frac{w(1+\Delta t) - W(\Delta t - \kappa t)}{D_0} + \kappa t\right)$$

It is of course necessary that the values of Δ and κ should have been determined previous experiments in the way already described.

Another, to some extent similar, method of measuring the cubical expansion of sol bodies, consists in determining their specific gravities at various temperatures, the bu of a given weight of a substance being inversely as its density.

In applying this method, the weight of water free from air which fills a specif gravity bottle at various temperatures is first ascertained; then, the weight of t bottle is determined at the same temperatures after a known weight of the substar

Digitized by Google

under examination has been put into it, and the interstices filled with water. Let W be the weight of water which fills the bottle at the temperature t, W' the weight of the solid substance, and S the weight of water and solid substance which together fill the bottle at $t°$; then the density of the substance at $t°$, compared with that of water at the same temperature, is $D_t = \frac{W'}{W-(S-W')}$; and if V_t represents the bulk which a unit-volume of water measured at 0° assumes at $t°$, the density of the substance at $t°$, compared with that of water at 0°, is $\frac{D_t}{V_t} = D_0$. Lastly, if the density D_0' of the substance at some other temperature $t'°$, has been determined in the same way, its mean coefficient of cubical expansion for one degree between t' and $t°$ is $\frac{D_0 - D_0'}{(t'-t)D_0}$.

The cubical expansion of a considerable number of crystallised compounds has al
been determined by Joule and Playfair (Chem. Soc. Qu. J. i. 121; for a tab
of the results, see also Gmelin's *Handbook*, i. 234).

From the determinations given at the beginning of this table, it will be seen th
the coefficients of expansion of solid bodies become greater as the temperature rise
but that the coefficient of expansion of platinum, which at the temperatures of t
experiments is very far from the point at which fusion or softening occurs, increas
much less than the coefficients of expansion of the more fusible metals, copper and iro
The rule thus indicated has been found to be verified in other cases also, so that wi
solids, as well as with liquids, the coefficients of expansion remain sensibly constant
temperatures far removed from those at which change of state occurs, and vary more a
more rapidly as these latter temperatures are approached.

The expansion of amorphous solids, and of those which crystallise in the regul
system (CRYSTALLOGRAPHY, ii. 121), is the same for all dimensions, unless when th
are subject to a mechanical strain in some particular direction. A fragment of such
substance varies in bulk with variations of temperature, but retains always the sam
shape.

Crystals not belonging to the regular system exhibit when heated an unequal e
pansion in the direction of their axes, in consequence of which the magnitude of the
angles becomes altered (Mitscherlich, Pogg. Ann. i. 125; x. 137). In crystals b
longing to the trimetric system, the expansion is different in the direction of all thr
axes; in arragonite, on raising the temperature from 0° to 100°, the inclination of t
lateral faces increases by 2′ 46″, and that of the terminal faces diminishes by 5′ 29
gypsum is, according to Fresnel (Bull. des Sc. Mathem. 1824, 100; also Pogg. An
ii. 109), more expanded by heat in the direction of the principal axis than in that
the lateral axes. In crystals belonging to the hexagonal system, the expansion is t
same in the directions of the three secondary axes; but different from that accordi
to the principal axis. The obtuse angles of the primitive rhombohedron of calcsp
diminish by 8½′ when the crystal is heated 100°, and the acute angles increase by t
same quantity. Hence it may be calculated that the relative expansion of the princip
axis (compared with that of the secondary axes) amounts to 0·00342; moreover sinc
according to Mitscherlich and Dulong, the cubical expansion of calcspar between 0° a
100° is only 0·001961, it may likewise be determined that calcspar, when thus heate
does not expand in the direction of the secondary axes, but *contracts* by 0·00056, a
that the absolute expansion of the principal axis may be estimated at 0·00286. In bitte
spar, the obtuse angle of the primitive rhombohedron diminishes when the temperatu
is raised from 0° to 100° by 4′ 6″, in ferruginous bitter-spar by 3′ 29″; in iron-sp
containing a considerable quantity of manganese, by 3′ 31″, and in pure iron-spar
2′ 22″. Since now, among all these minerals, calcspar forms the least, and ferrugino
bitter-spar the most obtuse rhombohedron, it follows that the expansion in the dire
tion of the principal axis does not increase in the same proportion as the relati
length of the axis itself diminishes (Mitscherlich).

The following direct determinations of the linear expansion of several crystallis
substances, between 0° and 100°, made by Pfaff (Jahresber. 1858, 7), show ve
distinctly the inequality in the amounts of expansion in the direction of the differe
axes.

Linear Expansion of Crystals between 0° and 100°

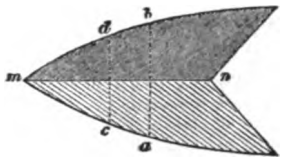
the form shown in *fig.* 537. From such a crystal, a portion *a b*, *c d* is cut, so that the new surfaces are perpendicular to the surface of combination, *m n*, of the two halves of the crystal, and the face *a b* is ground and polished. At the temperature of the atmo-

Fig. 537.



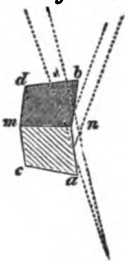


Fig. 538.

sphere, this surface then constitutes a single, unbroken plane; but when it is heated to about 60° or 80° C., the shape of the crystal alters in the manner shown in *fig.* 538, and now parallel rays of light falling on the two halves from a distant object are reflected in different directions, so that two distinct images of the object may be seen simultaneously by reflection from the surface *a b*.

One or two solid bodies are known which, at least within certain limits of temperature, form exceptions to the general rule of expansion by heat, and contract as their temperature is raised. For example, the alloy of 2 pts. bismuth, 1 pt. tin, and 1 pt. lead, expands when heated from 0° to 44° C.; when still further heated, it contracts, so that at 56° its density is the same as it was at 0°, and at 69° still greater; beyond this temperature, expansion again takes place; at 87·5° the alloy has once more the same density as at 0°, and at 94°, at which it fuses, the same as at 44°. (Erman, Pogg. Ann. ix. 557. For the not quite concordant results of H. Kopp, see below, p. 78.)

Again, a piece of vulcanised caoutchouc, which is stretched by a weight to double its length, is shortened by a tenth when its temperature is raised 50° C., and the shortening effect increases rapidly with the stretching weight employed. (Joule, Proc. Roy. Soc. viii. 356.)

Relation between the Specific Heats of Liquid and Solid Bodies, and their Coefficients of Expansion at different temperatures.—It has been pointed out above (p. 40), that the specific heat of any substance includes, not only the portion of heat required to cause in it a given alteration of temperature, but also the quantity of heat which is expended in modifying its condition of molecular equilibrium, and whose most obvious external effect is an alteration of the volume of the substance. We have also seen (p. 44), that although no certain data exist for calculating the ratio of these two parts of the total specific heat, except in the case of gases, it is nevertheless probable that the former part, or the *real specific heat* of a substance, remains the same for all conditions. Hence variations in the total or *apparent specific heat* must be supposed to result from variations in the amount of heat expended in overcoming the molecular forces. In sensibly perfect gases, the consumption of heat in this manner is the same at all temperatures, and so small as to be negligible; accordingly, both the real and apparent specific heats of gases are constant at all temperatures (pp. 34 and 42). On the other hand, the molecular changes which accompany alterations of temperature in liquid and solid bodies are such as require the expenditure of very considerable quantities of heat to produce them. These changes doubtless consist in alterations of the relative position or arrangement of the molecules, but of what precise kind we have no means of ascertaining, since the only measurable portion of the total effect is the externally visible change of volume.

This change of volume cannot be taken as in every case a measure of the amount of molecular work performed by the heat independently of causing alteration of temperature; for, as we have seen (p. 59), the communication of heat to water below 4° C. causes a change of bulk of the opposite kind to that which it occasions above that temperature; but we may nevertheless probably admit without great error that, as a general rule, the proportion of the total quantity of heat required to raise the temperature of a given substance 1°, which is consumed in producing molecular changes, is greatest at those points of the thermometric scale at which the greatest amount of expansion accompanies a rise of temperature of 1°, and is least at those points at which the corresponding expansion is least. If this supposition be admitted, it accounts satisfactorily for the fact that both the specific heats of solid and liquid bodies and their coefficients of expansion increase, as a rule, with rise of temperature; and that both

these properties vary most rapidly in the neighbourhood of those temperatures which changes of the state of aggregation occur (Comp. Verdet, *Exposé de la Thé Mécanique de la Chaleur*, Paris, 1863, note G, pp. 133 *et seq.*; also Regnault, M Acad. Sciences, xxvi. 285 *et seq.*) On the relations between changes of volume produ by external forces and the corresponding evolution or disappearance of heat, see bel Relations of Heat to Mechanical Energy.

3. *Changes of State of Aggregation produced by Heat.*

Fusion and Solidification.—When the temperature of a solid body is rai continuously, a point is reached sooner or later at which it melts, or exchan the solid for the liquid form; and when a liquid is cooled, a point is in like man attained at which it solidifies. With most homogeneous substances, the passage fr the one state to the other takes place suddenly at some particular temperature; t ice, when heated from a lower temperature to 0° C., becomes only very slightly so or less solid, while if more heat still is imparted to it, it changes at once into perfe liquid water. This temperature forms a definite limit below which we have solid and above which we have liquid water, and it is therefore called the *melting poin* ice. Some substances, however, pass when heated from the solid to the liquid st without showing any definite melting point; for example, glass and iron bec gradually softer and softer when heated, and pass by imperceptible stages from solid to the liquid condition. Such substances may be said to begin to melt at lowest temperature at which perceptible softening occurs, and to be fully melted wl further elevation of temperature does not make them sensibly more fluid; but no p cise temperatures can be given as their melting points.

Subject to the qualifications hereafter stated, the following general laws may taken as applicable to the phenomena of fusion and solidification:—

1°. The state of aggregation of every substance is always the same at the sa temperature: when its temperature is raised, it melts at a certain fixed point, or pa from the solid to the liquid state, and when its temperature is lowered, it solidifies, passes from the liquid to the solid state, at a point which is also fixed, and is the sa as its melting-point. (For substances which melt gradually, a certain fixed inter must be substituted for a fixed point of temperature in the enunciation of this rule.)

2°. The communication of heat to a solid body at its melting point causes it to m but does not raise its temperature; so also the withdrawal of heat from a liquid at freezing point causes it to solidify, but does not lower its temperature.

3°. As a general rule, a sudden change of volume (usually an increase) accompan the passage from the solid to the liquid state.

We will proceed to consider each of these laws and the exceptions and modificati to which they are subject.

Melting and Freezing Points.—Though the temperature at which the pass from the solid to the liquid state takes place, and *vice versâ*, is constant (under same circumstances) for each substance, the melting and freezing points of differ substances vary within very wide limits. Thus sulphurous anhydride melts at − 8 (Mitchell, *Berzel. Jahresber.* xxii. 59), mercury at − 40°, bromine at − 7·3°, ice at phosphorus at + 44°, tin at 235°, silver at 1000°, platinum at 2000° (Deville a Debray). (For the melting points of particular substances, see the articles in t Dictionary where they are respectively described.)

These differences are sufficient to justify the conclusion that even those substan which have never been seen to melt, would do so at a sufficiently high temperature, a conversely that all liquids, even such as have never yet been frozen, would solidify exposed to a still more intense degree of cold. Indeed, in proportion as new methods producing extreme temperatures have been discovered, the number of infusible sol and non-solidifiable liquids has gone on diminishing continually. The only substan which can be considered really infusible are those which, when heated, undergo chemi alteration before their melting point is reached. The most infusible of all substan which are chemically inalterable by heat is, probably, carbon in the form of graphi and even this body was found by Despretz to soften when exposed to the heat produc by the electric current generated by 600 Bunsen's cells arranged in six series of 1 On the other hand, absolute alcohol, sulphide of carbon, and some other liquids ha never been solidified, but at the temperature produced by a mixture of liquid nitr oxide, solid carbonic anhydride, and ether, Despretz found that absolute alcohol beca so viscid that it did not run out on inverting the vessel that contained it.

In very many cases, it happens that a mixture of two or more substances melts a lower temperature than either of its components taken separately: thus, a mixture 1 part chloride of sodium with 2½ or 2¾ parts ice, melts at about − 20°; mixtures fatty acids melt at lower temperatures than the pure acids; the carbonates of potassi

Digitized by Google

and sodium melt more easily when mixed than either salt does alone; Rose's fusible alloy of 2 parts bismuth, 1 part tin, and 1 part lead, melts between 95° and 98°; an alloy of 1 or 2 parts cadmium with 2 parts tin, 4 parts lead, and 7 or 8 parts bismuth, melts between 66° and 71° (B. Wood); &c.

In homologous series of analogous organic compounds, the melting point of each term usually rises with its atomic weight.

Under particular circumstances liquids may be cooled below the melting point of the corresponding solid body, without solidifying. This occurs especially when they are cooled very slowly, and are at the same time protected from all mechanical disturbance. For instance water at perfect rest, and under a pressure somewhat greater than that of the atmosphere, may be cooled to −15° without freezing, but contact with a solid body or the slightest agitation is then usually sufficient to cause solidification to commence. The smaller the quantity of liquid operated upon, the lower is the temperature to which it can be cooled, and the greater the mechanical disturbance which it will support without freezing. Thus, Fournet (Ann. Ch. Phys. [3] xlvi. 203) has remarked the frequent occurrence of mists formed by particles of liquid water suspended in an atmosphere of which the temperature was 10, 12, or even 15 degrees below zero; and Sorby found that in glass tubes of 0·1 millimetre in diameter, water could be maintained in the liquid state as low as −17°.

Some remarkable phenomena of this kind have been also observed by Dufour (Ann. Ch. Phys. [3] lxviii. 370) in the case of liquids cooled without contact with any solid body. His method of experimenting was to suspend globules of the liquid under examination in some other liquid of the same specific gravity, but of lower freezing point, and in which it was insoluble. Water was examined while suspended in a mixture of chloroform and sweet oil of almonds; sulphur and phosphorus, in an aqueous solution of chloride of zinc; and naphthalene, in water. In the experiments with water, the spheres of this liquid which floated in the mixture of chloroform and oil were very rarely seen to freeze at 0°; in general, solidification occurred between −4° and −12°, the smallest globules, as a rule, remaining liquid to a lower temperature than the larger ones, some of them having been repeatedly seen still liquid at −18° or −20°. Agitation and the contact of solid bodies appears to have much less effect in causing the solidification of liquids cooled in this way than when they are cooled to the same extent in glass vessels. For instance, Dufour found that the globules of water in his experiments often did not solidify when displaced or violently deformed by a glass rod, and even that crystals of chloride of sodium, sulphate or nitrate of potassium, sugar, &c., would sometimes fall *through* a globule of water 5 millimetres in diameter, and cooled to at least −8°, without producing any effect. Contact with a fragment of ice, however, invariably caused immediate congelation.

By operating as above described, Dufour obtained globules of sulphur (melting point 115°) of 6 millimetres diameter still liquid at 40°, and globules of 0·5 millimetre diameter remained liquid for several days at 5° or 10°. Globules of phosphorus of considerable size were cooled to 20°, and globules of 1 or 2 millimetres diameter to 0° without solidifying. Globules of naphthalene (melting point 79°) were obtained still liquid at 40°.

When a liquid solidifies after having been thus cooled below its normal freezing point, the solidification takes place very rapidly, and is accompanied by a disengagement of heat often sufficient to raise its temperature from the point at which solidification begins up to its ordinary freezing point. This is well seen with crystallised hyposulphite of sodium ($S^2Na^2O^3$, $5H^2O$), which melts in its water of crystallisation at 45°, but when carefully cooled will remain liquid for a long time at the temperature of the atmosphere. If it be then caused to solidify, by agitation, or by throwing in a small fragment of the solid salt, the resulting rise of temperature is such as to be distinctly felt by the hand.

This phenomenon of continued liquidity, though seldom observed in so marked a degree as in the cases above mentioned, occurs so frequently to a less extent, that, when the temperature of transition from the solid to the liquid state or *vice versâ* is to be used as a mark of the chemical identity of a substance, it is much safer to determine the melting point than the freezing point, for the former temperature is not subject to variations of the same kind.

The following method is convenient for taking the melting points of substances in chemical investigations. Three or four glass tubes are drawn out till their sides become very thin and their bore nearly capillary, and into each is introduced a small quantity of the substance to be examined. They are then sealed at the bottom and placed in a beaker-glass containing water (or, if the substance melts above 100°, paraffin or sulphuric acid), and standing upon a small sand-bath by means of which its temperature can be slowly raised. The liquid is heated until the substance melts; then allowed to cool slowly to the point of solidification; it is then again warmed, and

Digitized by Google

these operations are repeated, the temperatures of liquefaction and solidification being noted each time, until several closely concordant observations of each have been obtained, the means of which are the melting and solidifying points required.

Influence of Pressure upon Melting Points.—The variations which occur in the pressure of the atmosphere are without perceptible effect in altering the melting points of solids or freezing points of liquids, but greater differences of pressure are found to produce a very sensible effect. This was first observed by Prof. W. Thomson, who found that pressures of 8·1 and 16·8 atmospheres caused a lowering of the melting point of ice to the extent of 0·059° and 0·129° respectively. These results, therefore, verified the previous theoretical conclusions of Prof. J. Thomson, according to which an increase of pressure amounting to n atmospheres must lower the melting-point of ice by $t° = n \cdot 0{\cdot}0075°$,—a formula which gives 0·061° and 0·126° as the differences of melting point corresponding to 8·1 and 16·8 atmospheres pressure. By a still greater pressure, Mousson (Ann. Ch. Phys. [3] lvi. 252) succeeded in maintaining water in the liquid state at 5 degrees below zero, and by a pressure estimated at 13,000 atmospheres he caused ice to melt at —18°. Analogous effects have been observed with other substances by Bunsen (Jahresber. über Chemie, u. s. w., 1850, 48) and Hopkins (*ibid.* 1854, 48). Their results are given in the following table. Bunsen considers that the observations of temperature in his experiments were correct within 0·1°, but that there may be an error of one or two atmospheres in the estimation of the pressures.

Latent Heat of Fluidity.—It has been pointed out already (p. 73) that the specific heats of solid bodies increase as they approach their melting points, and this fact has been connected with the increase of the coefficient of expansion which generally occurs simultaneously. In order to raise the temperature of a solid body 1 degree in the neighbourhood of its melting point, more heat is needed than would suffice to cause an equal rise of temperature at a lower part of the thermometric scale; in other words, of a given quantity of heat imparted to a body near its melting point, a larger proportion goes to produce molecular modifications (expansion, softening, &c.), and a smaller proportion to produce rise of temperature, than is the case at a lower part of the scale. From this point of view, it becomes quite conceivable that, at some particular temperature, depending on the nature of the substance under consideration, the whole quantity of heat communicated to a body might be expended in causing molecular changes (change of the state of aggregation, with or without change of volume, &c.), so that its effect in producing a rise of temperature would be imperceptible. This is exactly what takes place during the melting of solid bodies.

From these considerations we see that the phenomenon indicated in the second law of the passage from the solid to the liquid state of aggregation (p. 74), is one which attains its maximum degree of development at the point of actual liquefaction, but is the same in kind as what occurs at lower temperatures. We see also that the fusion of glass and other bodies which have no definite melting point, but in which liquefaction occurs gradually and extends over a greater or less interval of temperature, does not differ in any essential respect from the sudden melting of ice at the fixed temperature of 0° C. In the case of glass, a certain small proportion of the total quantity of heat imparted to it during its liquefaction, is expended in causing elevation of temperature; in the case of ice, this proportion is so small as to be imperceptible in comparison with that which goes to cause liquefaction.

It was formerly supposed that the temperature of a body was always proportional to the heat contained in it, and therefore that heat could not be communicated to a body without raising its temperature. The cessation of the rise of temperature during the fusion of solids was first observed by Black, while Professor of Chemistry in the University of Glasgow. He ascertained that, during this process, a considerable quan-

Digitized by Google

tity of heat, different for different substances, disappears so far as the production of thermometric effects is concerned—or, as he expressed it, becomes *latent*—and that an equal quantity of heat appears during solidification. According to modern views, the expression *latent* (or hidden) *heat* is not strictly correct, for the effect of heat imparted to ice at the melting point is just as visible, though not the same, as that which it produces at other temperatures. Nevertheless, the expression is convenient from the fact of its being universally recognised and employed. The latent heat of fluidity is, then, the quantity of heat which must be imparted to one gramme of a solid at its melting point in order to melt it without raising its temperature, or which must be withdrawn from a liquid at its freezing point, in order to render it solid without lowering its temperature.

The following table gives the melting points and latent heats of fluidity, expressed in ordinary heat-units (gramme-degrees), of various substances, according to the determinations of Person (Ann. Ch. Phys. [3] xxvii. 250):—

Latent Heats of Fluidity.

Substance.	Melting Point.	Latent Heat.	Substance.	Melting Point.	Latent Heat.
Mercury . .	−39°	2·82	Tin . . .	235°	14·25
Phosphorus . .	44	5·0	Silver . . .	1000	21·1
Lead . . .	332	5·4	Zinc . . .	433	28·1
Sulphur . . .	115	9·4	Chloride of calcium ($CaCl_2 3H^2O$)	28·5	40·7
Iodine . . .	107	11·7			
Bismuth . .	270	12·6	Nitrate of potassium	339	47·4
Cadmium . .	320	13·6	Nitrate of sodium .	310·5	63·0

The latent heat of water was found by Regnault and by Provostaye and Desains to be 79° C. According to Person, this number denotes the quantity of heat required to convert ice at 0° C. into water, but not the total quantity of the latent heat in the water, inasmuch as a certain additional portion of heat is rendered latent as the temperature of the ice rises from −2° to 0° (Ann. Ch. Phys. [3] xxx. 73). In six experiments on the fusion of ice previously cooled to between −2° and −21° C., the latent heat was found to vary between 79·9° and 80·1°, the mean quantity being 80°. Regnault also found greater values for the latent heat of water, as the ice had been cooled to a lower temperature. According to Hess, the true latent heat of water is 80·34° C. It has been proved by E. Desains (Ann. Ch. Phys. [3] lxiv. 419) that when water is cooled below 0° without freezing, the quantity of heat needed, in order to raise the temperature of a given weight from $s°$ below zero to $t°$ above zero, is the same whether the water remains liquid all the time, or whether it first freezes and afterwards melts again.

It is interesting to compare these values of the latent heat of water with those found by Black in 1762 (*Lectures on the Elements of Chemistry*, 2 vols. 4to. Edinburgh, 1803: vol. i. pp. 120–127). In one experiment, this philosopher measured the time required for the conversion of a known quantity of ice at 32° F. into water at 40° F. in a room of which the temperature remained constantly at 47° F., and compared it with the time during which the temperature of an equal weight of water rose under similar circumstances, from 33° F. to 40° F. He thus obtained for the latent heat of water the number 139° F., equal to 77·2° C. In another experiment, he melted 119 parts of ice at 32° F. by immersing it in 135 parts of water at 190° F., and so obtained 254 parts of water at 53° F. Hence, taking into account the different specific heats of the water and of the glass in which it was contained, he deduced the number 143° F., equal to 79·44° C.

The method adopted by Black in the second of these experiments is essentially the same as that still employed for the determination of latent heats of fluidity. A known weight of the substance to be examined is heated to a known temperature, and then immersed in the water (or other liquid) of a calorimeter, the temperature of which is such as to cause the substance to melt if solid, or, if liquid, to solidify; and when uniformity of temperature is established in the calorimeter, this temperature is determined. The experiment is therefore quite similar to the determination of the specific heat of a substance by the method of mixtures; the same apparatus may be used and the same precautions require to be taken in the two cases (see pp. 25–29).

In such an experiment let

A be the weight of water in the calorimeter, the water-equivalents of the calorimeter and thermometer supposed included;

W, the weight of substance operated upon;

Digitized by Google

t, the initial temperature of the calorimeter;
θ, the final temperature of the calorimeter;
T, the initial temperature of the substance;
$\mathfrak{T}$, its melting (or freezing) point;
C, the specific heat of the substance in the solid state between the temperatures $\mathfrak{T}$ and θ;
c, its specific heat in the liquid state between the temperatures T and $\mathfrak{T}$; and
L its latent heat of fluidity.

Suppose that the experiment is made upon a melted substance which gives out heat to calorimeter and solidifies in it: then it is plain that the quantity of heat $A(\theta - t)$ absorbed by the calorimeter is made up of three parts—first, the heat lost by the substance in cooling from its original temperature to its freezing point; secondly, the heat given out by it during solidification; thirdly, the heat which it loses while cooling from its freezing point to the final temperature of the calorimeter. That is, $A(\theta - t) = W[c(T - \mathfrak{T}) + L + C(\mathfrak{T} - \theta)]$;

whence $$L = \frac{A}{W}(\theta - t) - c(T - \mathfrak{T}) - C(\mathfrak{T} - \theta).$$

The manner in which this formula will require to be modified, in order that it may apply to the case of a solid substance which is melted in the calorimeter by absorbing heat from it, need not be specially pointed out.

Changes of Volume accompanying Fusion and Solidification.—The accelerated rate of expansion exhibited by most solids as they approach their melting points, is in most cases followed by a further expansion during the actual process of liquefaction, so that the melted substance occupies a greater bulk than the solid of the same temperature from which it is formed. This phenomenon has been particularly studied by Kopp (Ann. Ch. Pharm. xciii. 129), whose principal results are as follows:

Phosphorus (the yellow modification of specific gravity 1·826 at 10°), expands uniformly up to its melting point (44°), at which temperature its volume is 1·017 of what it was at 0°; when melted, its volume at the same temperature is 1·052 of the volume at 0°. Hence 100 vols. solid phosphorus at 44° become 103·4 vols. liquid phosphorus at the same temperature.

Sulphur (native crystals, specific gravity 2·069) expands irregularly near its melting point (115°). Its volume being 1 at 0°, is 1·010 at 50°; 1·037 at 100°; 1·096 at 115°; at the moment of fusion, the expansion amounts to 5 per cent., the volume then increasing to 1·150.

Wax (bleached bees'-wax, specific gravity 0·976 at 10°) expands very rapidly as it approaches its melting point (64°), but only 0·4 per cent. more at the moment of fusion. If the volume at 0° is 1, the volume at 50° is 1·068; at 60°, is 1·128; at 64°, is 1·161, and increases by fusion to 1·166.

Stearic acid (pure, specific gravity nearly 1·0 at 10°) expands less than wax before melting, but then expands as much as 11·0 per cent. The volume at 0° being 1, it is 1·038 at 50°; 1·054 at 60°; and 1·079 at 70°, at which temperature the acid melts, its volume increasing to 1·198.

Rose's fusible metal (2 pts. bismuth, 1 pt. tin, and 1 pt. lead; specific gravity 8·906 at 10°) expands, when heated from 0° to 59°, in the ratio of 1 to 1·0027; but contracts when further heated, its volume at 82° being equal to that at 0°, and at 95° equal to 0·9947; in melting, between 95° and 98°, it expands by 1·55 per cent., so that at 98° its volume is equal to 1·0101. This alloy, therefore, contracts from 59° up to its melting point.

Water presents a remarkable exception to the general rule, and expands at the moment of fusion, or contracts on melting by about 10 per cent. One volume of ice at 0° gives 0·918 volume of water at the same temperature, or 1 volume of water at 0° gives 1·102 volume of ice. Dufour found, as the mean of 24 experiments, the density of ice at 0° equal 0·9175, that of water at the same temperature being 1. Brunner found for the density of ice the number 0·918.

Solid hydrated salts, on the contrary, expand at the moment of fusion, *e.g.* chloride of calcium ($CaCl^2.6H^2O$), by 9·6 per cent.; ordinary phosphate of sodium ($PNa^2HO^4.12H^2O$) and hyposulphite of sodium ($S^2Na^2O^3.5H^2O$) each by 5·1 per cent.

The expansion which takes place in water at the moment of solidification affords an explanation of several important phenomena. In the first place, it enables us to understand why increase of pressure should retard the freezing of water, instead of facilitating it, as it does that of most other liquids. Since the tendency of both heat and pressure is to diminish the bulk of water at 0°, and therefore to oppose the change of volume that occurs on freezing, it is easily conceivable that the one influence may (at least within certain limits) replace the other, and that a strong pressure applied to water at or below 0° may as effectually prevent its solidification, as the communication

Digitized by Google

of heat which would raise its temperature above the freezing point. In the case of substances whose volume in the solid state is less than their volume in the liquid state, pressure acts in the opposite sense to heat, and therefore retards liquefaction and promotes solidification.

This same phenomenon is the cause of the powerful mechanical effects which occur when water freezes in a confined space. The bursting of water-pipes, and the breaking of jugs containing water, during frosty weather, are among the most familiar of these effects; and to these may be added the splitting of rocks by the freezing of water in their fissures and the swelling up of moist ground during frost.

The force with which water expands when cooled, and at the moment of becoming ice, is strikingly illustrated in the experiments made by Major Williams, at Quebec. Having filled a 13-inch iron bomb-shell with water, he closed the hole left for introducing the fusee by driving firmly in an iron plug weighing nearly 3lbs., and exposed it in this state to the frost. After some time, the iron plug was forced out with a loud explosion and thrown to a distance of 415 feet, and a cylinder of ice, 8 inches long, issued from the opening. In another experiment, the shell burst before the plug was driven out, and in this case a sheet of ice spread out all round by the crack. If we take into consideration the experiments of W. Thomson and Mousson already recorded (p. 75), it seems probable that some of the water must have remained liquid in these experiments, up to the moment when the resistance was overcome; that it then issued from the shell in the liquid state, but at a temperature below 0°, and therefore instantly began to solidify when the pressure was removed, and so retained the shape of the orifice whence it issued.

Bismuth, cast iron and antimony expand like water on becoming solid.

Solution of Solid Bodies in Water.—Very many solid substances are capable of dissolving in water, and thus forming with it a uniform mixed liquid. As a general rule, the solvent power of water increases with its temperature, but this is not universally the case; for example, chloride of sodium has very nearly the same solubility in cold water that it has in boiling water; lime-water saturated at 0°, contains nearly twice as much lime as can be dissolved by the same quantity of water at 100°. Several other calcium-compounds exhibit similar properties; thus the sulphate is more soluble in cold than in boiling water, and becomes quite insoluble in water between 140° and 150° (Cousté, Ann. des Mines, [5] v. 143). Sulphate of sodium is more soluble in water at 33° than at other temperatures, higher or lower, and has about the same solubility at 0° that it has at 100°. From the experiments of Sullivan (Rep. Brit. Association, 1859, p. 292) it appears that the solubility of very many salts attains a maximum at some particular temperature, above which it diminishes. Hence, perhaps, the reason why the solubility of most solids is commonly supposed to increase continuously as the temperature rises, is that it has been determined only at temperatures below 100°, and that the points of maximum solubility for most substances lie higher. If this be so, the solubility of sulphate of sodium,—and of the few other salts (selenate of sodium, sulphate of iron) in which similar properties have been observed,—is only in so far anomalous, that its temperature of maximum solubility is lower than that of most other substances. Water which is saturated at a given temperature with one substance can usually dissolve an additional quantity of another.

The liquefaction of solid bodies by solution in liquids, obeys essentially the same laws as their liquefaction by the direct application of heat. It is facilitated or retarded in the same way by great variations of pressure, and is attended by the absorption of a certain quantity of heat, which is evolved again when the dissolved substance separates from solution in the solid form; usually also the volume of the solution differs from the combined volumes of solid substance and water at the same temperature; and, lastly, solutions present the phenomenon of supersaturation, analogous to that of the deferred solidification of liquids.

As might be expected from the analogy with the liquefaction of solid bodies in general, increased pressure favours solution in cases where, as is usual, the volume of the water and dissolved substance is less after solution than the volume of the water and substance when separate; and diminishes the solubility of substances whose volume when dissolved is greater than their volume in the solid state, together with that of the water. (Comp. Sorby, Proc. Roy. Soc. xii. 538, also, Möller, Jahresber. 1862, pp. 11–13.)

The absorption of heat which occurs during solution is taken advantage of by the chemist for the artificial production of low temperatures. The table on the next page gives a few of the most frequently useful freezing mixtures, with the reduction of temperature which can be produced by means of each. In order to obtain the greatest possible effect by the use of any of these mixtures, it is necessary to use a considerable quantity of the materials (2 or 3 pounds at least); otherwise the whole heat required for the liquefaction is furnished by the containing vessel, and the whole of the mixture

Digitized by Google

becomes liquid before its temperature has been much reduced. It is also of importance that the materials should be mixed as intimately as possible. Other more powerful freezing mixtures, depending on the employment of condensed gases, will be described hereafter.

Table of Freezing Mixtures.

Ingredients of the Mixture.	Parts by Weight.	Temperature produced, starting from 10°.	Diminution of Temperature.
Water	1	−16°	26°
Nitrate of ammonium	1		
Water	16	−12°	22°
Nitrate of potassium	5		
Chloride of ammonium	5		
Water	1	−19°	29°
Nitrate of ammonium	1		
Carbonate of sodium	1		
Snow, or pounded ice	5		20°
Chloride of sodium	2		
Snow, or pounded ice	1		45°
Crystallised chloride of calcium	2		
Crystallised sulphate of sodium	8	−20°	30°
Hydrochloric acid	5		

From a table already given (p. 60), it will be seen that water containing saline substances in solution freezes at a lower temperature than pure water, and that the depression of the freezing point increases with the quantity of substance in solution. This latter point is proved still more distinctly by the more recent experiments of Rudorff (Phil. Mag. [4] xxii. 552), from which it appears that the depression is very nearly in exact proportion to the quantity of salt dissolved. The ice which forms from a dilute solution of a salt yields nearly pure water when melted.

When a saturated solution is cooled, the excess of dissolved substance, beyond that which saturates the liquid at the lower temperature, generally separates out in the crystalline form; sometimes, however, especially if the solution is cooled slowly and is kept at perfect rest, a condition of unstable equilibrium may arise, like that of liquids cooled below their ordinary freezing points without solidifying, in which a greater quantity of substance is retained in solution than the liquid would be capable of dissolving if it were put in contact with it in the solid form. In this state, solutions are said to be supersaturated; and the same causes are in general sufficient to cause the separation of the excess of dissolved substance, as cause the solidification of over-cooled liquids.

If an aqueous solution of a salt is boiled in a flask of which the neck is drawn out to a fine point, and if the point is then hermetically sealed when all the air has been expelled, the solution very frequently remains supersaturated when cold; but on breaking the point, so as to readmit the air, even if this is done without shaking the solution in the least, or allowing the smallest fragment of glass to fall into it, crystallisation in most cases begins. If, however, the air that enters the flask has been previously passed through a red-hot tube, or even if it has been merely filtered through a column of cotton wool, crystallisation does not take place (comp. Loewel, Jahresber. 1852, p. 359; Schröder, Ann. Ch. Pharm. cix. 45; also particularly Gmelin's *Handbook*, i. 9–11). The most probable explanation of this difference is that the solid particles of soluble matter contained in the unheated or unfiltered air, disturb the molecular equilibrium of the solution by dissolving in it, and so cause crystallisation to begin. This explanation is confirmed by the fact that a supersaturated solution frequently does not crystallise if stirred with a glass rod or platinum wire which has been recently heated to redness, but crystallises instantly if touched with a rod that has lain long exposed to the air.

By cooling supersaturated solutions below 0°, they may be brought into such a condition, that either ice or the dissolved salt will crystallise out according to circumstances. Thus Rudorff found (*loc. cit.* and Pogg. Ann. cxvi. 55) that a small fragment of ice, thrown into a strongly cooled solution of platinocyanide of magnesium or sulphate of sodium, caused a crystallisation of ice, the whole of the salt remaining dissolved, until a very large proportion of the water had been transformed into ice; while a fragment of the solid salt thrown in caused the salt to crystallise, but no ice. The crystals of ice and of the salts used in these experiments were easily distinguishable by their

Digitized by Google

different colours and specific gravities. These results are quite analogous to the simultaneous separate crystallisation of two or more salts contained in the same solution.

Vaporisation and Condensation.—When a quantity of water or alcohol is left exposed to the air, it gradually disappears, owing to its transformation into a transparent, invisible vapour, which diffuses into the atmosphere. This formation of vapour at the free surface of a liquid constitutes evaporation. It takes place more or less rapidly with all liquids, except some of those which are easily decomposed by heat when their temperature is sufficiently high. Some liquids, such as water, evaporate at all temperatures, but this is not the case with all: for instance, mercury gives off no sensible quantity of vapour at -10°, and two basins may be placed near each other, under an exhausted receiver, at the ordinary temperature, one containing oil of vitriol and the other a solution of chloride of barium, without the smallest precipitate being formed in the latter. Some solid bodies, *e.g.* ice, iodine, camphor, give off vapour without previously passing into the liquid state; and it is proved by Regnault's experiments (upon benzene, bromide of ethylene, glacial acetic acid, chloride of cyanogen, and chloride of carbon), that substances which are capable of existing at the same temperature either as solids or liquids, produce, in both states of aggregation, vapours of equal tension (see next paragraph).

Fig. 539.

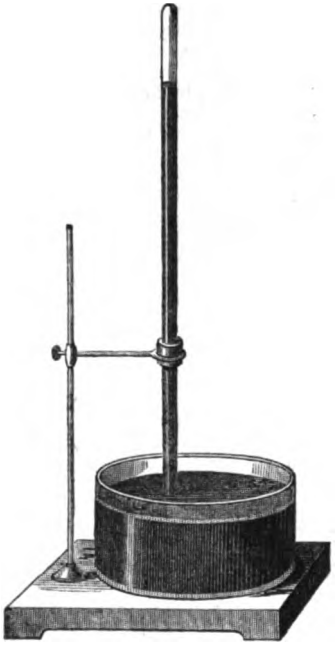

Fig. 540.

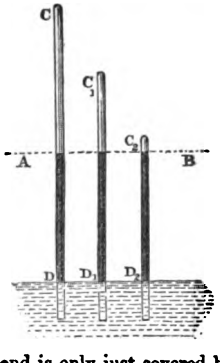

Tension of Vapours.—The quantity of any given liquid which can evaporate in an enclosed space, either previously vacuous or already containing a gas or vapour, is limited, and depends on the nature of the liquid, on the temperature, and on the extent of the enclosed space. When the liquid is in excess, that is, when some of it remains after the formation of the largest quantity of vapour that is possible under

Digitized by Google

the circumstances, evaporation ceases when the vapour exerts a certain pressure upon the sides of the containing vessel. The laws of evaporation are, therefore, most easily arrived at by studying, in the first instance, the phenomena of the formation of vapour in a vacuum, in which case the pressure exerted by the vapour itself is the only one to which the sides of the vessel are exposed.

If a glass tube, closed at one end, about a yard long and three-quarters of an inch wide, is filled with mercury and inverted in a basin of that liquid, as shown in *fig.* 539, a vacuous space, about six inches in length, is formed at the top of the tube. On now passing up a drop or two of ether or alcohol into this space, the liquid will immediately evaporate, so that the surface of the mercury and of the tube will remain dry, but the mercury column will be depressed by the elastic force of the vapour which has been formed. The amount of this elastic force, or of the pressure which the vapour exerts upon the sides of the tube and upon the top of the column of mercury, is evidently measured by the difference between the height of this column and that of the barometer at the time of the experiment. On transferring the tube in this condition to a mercury-trough provided with a deep cylindrical well (*fig.* 540), and depressing it slightly, the space occupied by the vapour above the mercury will be diminished; the tension of the vapour will therefore increase, and the mercury column A C will be still further depressed. But on continuing to diminish in this way the volume of the vapour, a point will soon be reached at which part of it returns to the liquid state and condenses as a dew upon the inside of the tube and on the mercury; and if the height of the column A C be measured, as soon as the first trace of condensed liquid becomes visible, it will be found to remain the same until the tube has been depressed so far that the whole of the vapour has been converted into liquid, and the tube becomes filled with mercury, surmounted by a drop of liquid ether or alcohol. The progress of the experiment in this stage will be easily understood from *fig.* 541, where C D represents the tube when the liquid first begins to appear in the space above the mercury, and A B the level of the mercury in the tube above that in the trough. As the tube is depressed successively to the positions C_1 D_1, and C_2 D_2, more and more of the vapour is liquefied, but the remaining portion exerts neither more nor less pressure than the quantity which existed in the tube at the instant when liquefaction first began to take place; and hence the surface of the mercury remains immovably at the level A B. Again, if the tube is raised up out of the mercury, the top of the mercury column will still remain at the level A B, until the whole of the liquid has again evaporated into the space above it, but from this point it will begin to rise higher and higher as the tube is still further raised; if, however, when the tube has attained its highest position (so that the open end is only just covered by the mercury in the trough), an additional quantity of ether or alcohol is passed up into it, the column of mercury will sink; and if the quantity of liquid passed up is more than can evaporate in the portion of the tube unoccupied by the mercury, the surface of the latter will sink again to the level A B (*fig.* 541).

Fig. 541.

These experiments prove that when a vapour is compressed, its temperature remaining always the same, its elastic force increases up to a certain limit which it cannot exceed, the effect of any further compression being to change it to a liquid; and that when a vapour is in contact with any portion of the corresponding liquid, in a space otherwise vacuous, its elastic force always attains this limit, whatever may be the relative volumes of vapour and liquid. In this condition, a vapour is said to be **saturated**, or to exert its **maximum tension**.

Maximum Tension.—The maximum tension which the vapour of any liquid can exert depends upon the nature of the liquid, and upon its temperature.

If we pass up into the first of three barometric tubes, like that represented in *fig.* 539, a small quantity of ether, into the second some alcohol, and into the third some water, taking a larger quantity of each liquid than can evaporate completely within the tube, the mercury column will be depressed to a different level in each, supposing all three to have the same temperature. If, for instance, the temperature is 10° C., the mercury will be depressed about 11¼ inches in the first tube, nearly 1 inch in the second tube, and a little more than ⅓ inch in the third.

If the three tubes are now gradually heated, by surrounding them with warm water or otherwise, more vapour will be formed from the liquid contained in each of them; the elastic force or tension of each vapour will accordingly increase, and the mercury will descend lower and lower in the tubes as the temperature rises. At about 35°, the tension of the ether-vapour will have become equal to that of the atmosphere, and hence at this

Digitized by Google

temperature, the mercury in the tube containing it will have been driven down so as to be at the same level as that in the reservoir; at about 78·5° the same will be the case with the mercury in the alcohol-tube; and at about 100° with that contained in the water-tube.

When a saturated vapour is cooled, the pressure upon it remaining unaltered, complete liquefaction takes place, just as it does when the pressure is increased and the temperature remains the same. The condition of saturation, or maximum tension, is therefore a limiting condition, beyond which a vapour can neither be compressed nor cooled without returning to the state of liquid.

On the other hand, when a saturated vapour not in contact with an excess of liquid is heated, it ceases to be saturated (unless the pressure upon it is increased at the same time to a corresponding extent). Hence, when a further quantity of liquid is brought in contact with a vapour which has been thus heated, more vapour is formed in the same space, until saturation is again produced, and the tension increases at the same time till it reaches the maximum tension corresponding to the higher temperature.

Distinction between Vapours and Gases.—It has been already stated, that when the space into which a liquid can evaporate is increased until the whole quantity of liquid has become vapour, the tension of the vapour diminishes with any further increase of volume; and that when a vapour, not in contact with the liquid from which it is formed, is compressed, its tension augments until liquefaction begins. In proportion as a vapour under these conditions is expanded, its tension becomes more and more nearly inversely proportional to the volume which it occupies; that is, its properties approach more and more nearly to those of a perfect gas. Similarly, when a saturated vapour, not in contact with an excess of liquid, is heated, its elastic force increases, and it expands if the pressure upon it is not proportionably augmented; and as the temperature rises, the relation between the tension or elastic force, p, of the vapour, its volume, v, and its temperature, t, comes to be more and more nearly expressed by the equation

$$pv = J(a + t);$$

which, as we have already seen (p. 45), expresses the relation between these three quantities in the case of a perfect gas (see also p. 50).

Hence the physical properties of vapours, when sufficiently expanded, and at sufficiently high temperatures, are identical with those of the permanent gases.

From this it is natural to conclude, conversely, that the so-called permanent gases themselves are only vapours which, at ordinary pressures and temperatures, are very far removed from their points of saturation, and that by exposing them to lower temperatures and increasing the pressure, a point might be reached for each of them, at which the pressure would be equal to the maximum tension which it was capable of exerting at the temperature of the experiment, and therefore, that any further diminution of temperature or increase of pressure would cause it to become liquid. This conclusion has been actually verified in the case of many gases formerly regarded as permanent, the only gases which have hitherto resisted all attempts to liquefy them being hydrogen, oxygen, nitrogen, nitric oxide, carbonic oxide and marsh-gas. (The methods employed for the liquefaction of gases will be further considered in connection with the processes adopted for obtaining great reductions of temperature.)

Tension of Vapours in presence of Permanent Gases.—The familiar fact of the evaporation of water in the open air affords sufficient proof that the presence of a permanent gas in any given space does not prevent volatile liquids giving off vapour into the same space. By measuring the volume and elastic force of a given quantity of dry air, or other gas, then introducing a little more of any liquid than can completely evaporate in it, and when equilibrium has been re-established, again measuring the volume and elastic force of the mixture of gas and vapour, the tension of the latter can be ascertained. In this way it has been found that, when the liquid exerts no solvent or chemical action upon the gas, the combined tension of gas and vapour is nearly equal to the separate tension of the gas, increased by the maximum tension which the vapour is capable of exerting in an otherwise vacuous space at the temperature of the experiment. In other words, the vapour given off by a liquid at any temperature has nearly the same maximum tension, whether it is formed in a space previously vacuous or filled with a permanent gas. The only essential difference between the evaporation of a liquid in a vacuum, and its evaporation in a gas, is that, in the former case, the vapour attains the condition of saturation in an inappreciably short time, while in the latter, this condition is arrived at more slowly. Regnault's experiments (Mém. Acad. Sciences, xxvi.) prove, however, that liquids do not give off vapour of quite so great a tension in a space occupied by a permanent gas, as they do in a vacuum, and that the difference increases as the temperature rises.

Boiling Points.—Ebullition.—From the facts stated in the last paragraph, it follows

Digitized by Google

that the temperature at which the vapour of a liquid introduced into the barometric vacuum would exert sufficient elastic force to drive the mercury down to the bottom of the tube, so as to make it stand at the same level inside and outside, is also the temperature at which the vapour formed on heating the liquid in the air would exert an elastic force equal to the atmospheric pressure. As already stated, the first of these effects is produced by ether-vapour at 35°, by alcohol at 78·5°, and by water at 100°: these temperatures, however, are those at which the liquids respectively boil when heated in the open air, the barometer being at its average height. The boiling point of a liquid is, therefore, the temperature at which the tension of its vapour becomes equal to the atmospheric pressure. This temperature is evidently not absolutely constant for each liquid, but varies more or less with alterations of the pressure of the atmosphere. A liquid at its boiling point is in a limiting condition, comparable to that of a saturated vapour; any diminution of pressure or increase of temperature equally causes it to pass from the liquid to the vaporous state. The two conditions are in fact conterminous; and the temperature at which a liquid produces vapour of any given maximum tension, is also the temperature at which the liquid would boil under an atmospheric pressure equal to that tension. Hence the observation of the pressures under which a liquid boils at various temperatures constitutes a method of determining the maximum tension of its vapour at those temperatures.

The phenomenon of ebullition, which presents itself when heat is applied to the lower part of a mass of liquid, already at such a temperature that the tension of its vapour is equal to the pressure of the atmosphere, results from the transformation of the liquid into vapour at the points where the heat is applied, and the escape of this vapour in the form of bubbles through the superincumbent liquid.

The temperatures at which different liquids boil, under the ordinary atmospheric pressure, vary very greatly. They will be found given for each liquid in the article of this dictionary wherein it is specially described; in the following table a few boiling points are given in order to illustrate the range of temperature through which they occur.

Table of Boiling Points.

Liquid.	Boiling Point.	Pressure in millimetres of mercury.	Authority.
Nitrous oxide . .	−87·9°	759	Regnault
Carbonic anhydride .	−78·2	767·3	„
Ammonia . . .	−33·7	749·3	Bunsen

Determination of Boiling Points.—The boiling points of different liquids being among their most characteristic properties, the determination of them becomes a very frequent and important operation in chemical research. The method recommended by Kopp, in order to ensure as much accuracy as possible in these observations, is as follows:—

The liquid to be examined is placed in a cylindrical glass vessel, containing a few scraps of freshly ignited platinum foil, the diameter of which, when the quantity of liquid is small, need not much exceed that of the bulb of the thermometer. This vessel is closed by a cork, through the centre of which the thermometer is inserted, in such a way that it can be raised or lowered, so that the bulb may dip either into the liquid or

Digitized by Google

merely into the vapour. It is generally advisable to give the thermometer the latter position, since, as will be seen by what follows, the temperature of the liquid may, under circumstances which not unfrequently occur, rise somewhat above the true boiling point; but even when this is the case, a thermometer in the vapour will show the real boiling point of the liquid: under nearly all circumstances, the thermometer will stand lower in the vapour than it does in the liquid, if this is a mixture of two or more liquids of different boiling points instead of a pure, homogeneous substance. Through a second hole in the cork is inserted a glass tube, open at both ends, and bent at a right angle, as shown in *fig.* 542; by connecting this tube with a condenser, the loss of the liquid used for the experiment can be prevented. The liquid is heated either by applying a small flame to the outside of the vessel, or by means of a water-bath or sand-bath, care being taken that the sides of the vessel above the liquid do not get over-heated. The indications of the thermometer are observed during the whole time that the liquid is being slowly boiled away, until only a small quantity remains. The temperature thus observed is not, however, in most cases, the true boiling point of the liquid: usually, part of the mercury column in the thermometer rises above the cork, and is therefore exposed to a lower temperature than that of the boiling liquid; consequently, the upper extremity of the column stands at a lower point than it would do if the thermometer were completely immersed in the liquid. In order to find the correction which it thus becomes necessary to apply, a second thermometer is placed so that its bulb is in contact with the stem of the thermometer inserted into the cork of the boiling vessel, and is half way between the top of the mercury column of the latter thermometer and the middle of the cork. The temperature indicated by this second thermometer may be taken as the mean temperature of that portion of the mercury column of the principal thermometer which is not heated by the vapour of the boiling liquid. Let this temperature be $t°$; let the uncorrected boiling point, directly indicated by the principal thermometer, be $T°$; let N be the difference between T and the point of the scale situated at the middle of the cork, that is to say, the length, expressed in degrees of the scale, of that portion of the mercury column of the principal thermometer of which the mean temperature is $t°$; lastly, let δ be the coefficient of apparent expansion of mercury in the glass of which the thermometer is constructed. The correction to be applied to the directly observed temperature $T°$ is then

Fig. 542.

$$= N(T-t)\delta.$$

As already stated (p. 57), δ may always be taken, in calculating the value of this expression, as $= 0{\cdot}0001545$.

The table which follows on p. 86 gives the amounts of the correction in question for various values of N and of $T-t$. The amounts corresponding to other values of these factors can be easily deduced by interpolation from the numbers given in the table.

This table sufficiently shows that the correction in question can never be neglected in accurate experiments, and that in the case of liquids of high boiling points, its value may become very considerable.*

Since the boiling point of a liquid depends on the pressure to which the liquid is subjected, another correction becomes necessary in order to reduce determinations made under the varying pressure of the atmosphere, to the values which would be found if the atmosphere exerted always its normal pressure, equal to that of 760 millimetres of mercury at 0°. Strictly speaking, the correction to be applied to the boiling point of a liquid observed under an atmospheric pressure differing by a given amount from the above standard pressure, varies with the nature of the liquid; since equal alterations of pressure do not cause precisely equal changes in the boiling points of different liquids. Nevertheless, the greatest variations which ever occur in the pressure of the atmosphere are relatively so small, that they may, without any appreciable error, be regarded as affecting the boiling points of all liquids equally: to the extent, namely, of 0·1° for a variation of pressure of 2·7 millimetres of mercury, this number being deduced from direct determinations of the boiling point of water under different pressures.

In what follows, whenever the boiling point of a liquid is spoken of without further explanation, it is to be understood to mean the boiling point under a pressure equal to that of 760 millimetres of mercury at 0°.

* It is obvious that a precisely similar correction ought to be applied to all thermometric observations in which any portion of the mercury in the stem of the thermometer is at a different temperature from that in the bulb.

Circumstances which modify the Boiling Point.—Although, when a liquid is heated in such a manner that vapour can escape freely from some part of its surface, the vapour so formed has a tension equal to the pressure upon the free surface of the liquid as soon as the temperature of the latter reaches the boiling point, this temperature may nevertheless be attained, and even considerably exceeded, without the formation of a trace of vapour, if no portion of the surface of the liquid is freely exposed. These conditions can be realised by suspending the liquid to be examined in a second liquid of equal specific gravity, but higher boiling point.

The phenomena which take place under these circumstances have been particularly studied by Dufour (Ann. Ch. Phys. [3] lxviii. 378). In order to examine them in the case of water, he employed a mixture in the requisite proportions of oil of cloves (previously heated alone to about 200°) and linseed oil. The water, already heated to 80° or 90°, was dropped gently into the mixture of oils, so as not to disturb the film which coated the bottom of the vessel, and the temperature of the bath was gradually raised. Under these circumstances the ordinary boiling point of water, 100°, was passed without the occurrence of any perceptible change, and traces of ebullition scarcely began to show themselves below 110° or 115°. Even at these temperatures, ebullition seldom began except when the globules of water came in contact with the sides of the vessel or with the thermometer. A burst of vapour then occurred, and the globule, more or less diminished in size, was driven rapidly away, like a pith ball after touching an electrified conductor. These contacts were of course more difficult to avoid in the case of large than of small globules; hence the latter remained liquid, as a rule, to higher temperatures than the former.

In these experiments, it was a rare exception when ebullition occurred between 100° and 110°; very commonly globules of 10 mm. in diameter reached 120° or 130°, and in one experiment the last temperature was attained by a globule of 18 mm. diameter, and therefore containing more than 3 c. c. of water. Spheres of 10 or 12 mm. diameter often reached 140°; those of 5 or 6 mm. reached 165°; and others of from 1 to 3 mm. attained 175° or even 178°, temperatures at which the elastic force of the vapour which forms at the freely exposed surface of water is between 8 and 9 atmospheres.

At these high temperatures, the contact of a solid body very generally occasioned the sudden partial or complete vaporisation of the globules, accompanied by a hissing sound like that produced on immersing red-hot iron in water. This invariably occurred when the globules were touched with pieces of wood or chalk, shreds of cotton, paper, &c., but not always on contact with a glass rod or metallic wire, the difference appearing to depend on the porous structure of the former substances. A platinum wire appeared to lose, to some extent, by frequent usage, the power of causing sudden vaporisation.

Sudden ebullition, amounting even to an explosion, if the temperature was above 120°, invariably occurred on passing the discharge of a Leyden jar or induction coil through a globule. A similar, but less violent, effect was produced by the passage of a weak galvanic current. These results are attributed by Dufour less to the contact of the globules with the conducting wires, than to the disengagement of gas at the extremities of the latter.

Saturated aqueous solutions of various salts—for example, chloride of sodium, sulphate of copper, nitrate of potassium, &c.—also remained liquid at temperatures much above their boiling points, when immersed in melted stearic acid resting on a layer of melted sulphur. In like manner, globules of chloroform (boiling point 61°), suspended in a solution of chloride of zinc, often remained liquid up to 97° or 98°; and globules of liquid sulphurous anhydride (boiling point −10·5°) could be heated in diluted sulphuric acid as high as +8°. In all these cases, the same causes that operated in the case of water, sufficed to occasion the sudden complete or partial conversion of the overheated globules into vapour.

These results throw important light upon the nature of ebullition, and seem to indicate that it is to some extent an accidental phenomenon. In order to understand them, we must remember that, the globules being surrounded on all sides by liquid, evaporation cannot go on at their surface in the ordinary way. They are, however, in a state of tension, or unstable equilibrium, such that a very slight cause may occasion the sudden formation of vapour of more than the atmospheric tension. The most effectual of such causes would obviously be the contact of a minute globule of air or other gas: this globule, however small, would be a space into which vapour could be given off, and this vapour, having an elastic force greater than the pressure (that of the atmosphere and the upper layers of the liquid) whereby the globule was prevented from expanding, would force back the liquid walls of the bubble of gas, suddenly converting it into a large bubble of steam. Hence the unfailing efficacy, in causing the ebullition of the overheated globules of liquid, of the passage of an electric current or the contact

Digitized by Google

of porous substances, such as chalk, wood, paper, &c., which either allow air to esca from their pores when immersed in the heated liquid, or carry down into it sm globules of air adhering to them. These globules afford space for the *commencement* the formation of vapour, and this process being once begun, the space is increased the force of the vapour already formed within it. In the absence of any such spa the liquid globule is in a condition somewhat analagous to that of a drop of melted gl which has been suddenly cooled in water (Rupert's drops), and which falls to powd on receiving the smallest scratch: there is no reason why the formation of vapo should begin at one point of the mass rather than at another, and thus the whole remai in a state of molecular tension until something occurs at some particular point to weak the effect of the forces which oppose the formation of vapour, or until the tensi increases (in consequence of rise of temperature) to such a degree that these forces a overcome simultaneously throughout the whole mass. It will be seen further on th these considerations exactly agree with the explanation which the mechanical theo of heat affords of the passage from the liquid to the gaseous state.

Even when liquids are heated in open vessels, the occurrence of ebullition, or t formation of vapour in the *interior* of the mass, appears to depend on like accident causes. Thus the influence of the nature of the vessel wherein a liquid is contain has been long recognised. It has been observed, for instance, that water, which w boil steadily at 100° in a metallic vessel, may often be heated to 105° or 106° witho boiling, in a glass vessel previously washed with strong sulphuric acid. Under the circumstances, ebullition generally takes place very irregularly: at a certain temper ture a sudden burst of vapour occurs, and the temperature of the liquid falls at the sa time to nearly the normal boiling point; the liquid then remains tranquil for a tim until the temperature having again risen considerably, another burst of vapour tak place, and so on. The "bumping" of heated liquids which results from this inte mittent formation of vapour, is familiar to every chemist. It may be prevented to son extent by putting into the liquid a few scraps of platinum, or a globule of mercury; small piece of charcoal is, however, much more effectual than either of these, though n always admissible. This irregular ebullition occurs much more frequently in son liquids than others, and to a greater extent in certain glass vessels than in others. F instance, methylic alcohol (boiling point 61°) may show a difference in its temperatu of ebullition amounting, according to Kopp, to 5 or 6 degrees, depending on the ves in which it is examined. When a liquid is boiling steadily in a glass flask or reto it may almost always be noticed that the bubbles of vapour start from one or t particular points of the surface of the glass, indicating the existence of some irregulari of the glass at those points favourable to the formation of vapour. Another illustrati of the necessity of some other cause than mere temperature in order to bring about t ebullition of liquids, is afforded by the remarkable observation of Professor Donny, Ghent, that water thoroughly deprived of air and sealed up in a rather long glass tu quite free from air, may be heated to 138° at one end of the tube without boiling, a is then suddenly and violently thrown to the other end by a burst of vapour. A additional fact of the same kind may sometimes be observed during the distillation liquids under the ordinary pressure. The writer has occasionally seen a liquid dis very rapidly, thus showing that vapour was being formed rapidly at the surface, althou ebullition could not be maintained by the use of a more powerful flame than th which had sufficed, at an earlier stage of the experiment, to boil a larger quantity the same liquid.

The whole of these phenomena cease to be unintelligible if, with Dufour, we disti guish between the boiling point of a liquid, and the temperature at which the elast force of its vapour becomes equal to the pressure of the atmosphere, and define t boiling point as the lowest temperature at which ebullition *can* occur, instead of as t temperature at which, under normal conditions, it *must* occur.

Spheroïdal State.—When a drop of water is allowed to fall upon a piece of iron, t temperature of which considerably exceeds 100°, it retains its globular form, mov about rapidly on the surface of the iron without wetting it, and evaporates with con parative slowness. As the iron cools, a point is reached at which the globule of wat wets it, spreads over its surface, boils and quickly disappears. The condition of t globule first described has been distinguished as the spheroïdal state. Th condition can be assumed by all volatile liquids when they come in contact with th surface of either a solid or a liquid body heated considerably above their boiling point The temperature of a liquid in the spheroïdal state is always below its ordinary boilin point, notwithstanding the higher temperature of the surface on which it rests. Th absence of ebullition is therefore due in this case to some other cause than that whic produces the phenomena of deferred ebullition which were considered in the last paragraph It is the result of a want of perfect contact between the liquid and the heated surfac Many experiments prove that the liquid globule rests upon a sort of cushion of its ow

Digitized by Google

vapour, produced by the heat radiated from the hot surface against its under side. As fast as this vapour escapes from under the globule, its place is supplied by a fresh quantity produced in the same way, so that the globule is constantly buoyed up by it, and never comes into actual contact with the heated surface. If, however, the temperature of the latter is allowed to fall, the formation of vapour becomes less and less rapid, until at last it is not supplied fast enough to prevent the globule touching the hot metal or liquid on which it rests: as soon as contact occurs, heat is rapidly imparted to the globule, it enters into ebullition, and quickly boils away.

According to Boutigny's experiments, the lowest temperature at which a metallic vessel will cause the spheroïdal state to be assumed by water is 142°; for alcohol the lowest temperature is 134°, and for ether 61°.

Solid bodies which evaporate without becoming liquid also assume a condition analogous to the spheroïdal state of liquids, when they are placed upon a surface whose temperature is sufficiently high to vaporise them very rapidly. This is very distinctly seen on throwing a piece of solid carbonate of ammonium into a red-hot platinum crucible, and when a fragment of solid carbonic anhydride is placed upon any good conducting surface at the ordinary temperature.

Effect of Substances in Solution on the Boiling Point of Liquids.—Liquids holding solid bodies in solution boil generally at higher temperatures than they do in the pure state. On the other hand, the boiling point of water is lowered by mixing it with alcohol, and that of alcohol by mixing it with ether; the boiling point of a mixture being always intermediate between the boiling points of its components. The effect of salts in raising the boiling point of water may be considered as also coming under this rule. The following table gives the boiling points of saturated solutions of several salts, according to Legrand.

Table of Boiling Points of Saturated Saline Solutions.

Salt.	Weight of salt dissolved in 100 parts of water.	Boiling Point.	Salt.	Weight of salt dissolved in 100 parts of water.	Boiling Point.
Acetate of potassium .	798·2	169°	Tartrate of potassium .	296·2	114·7°
Nitrate of calcium .	362·2	151	Chlorate of potassium .	61·5	104·2
Carbonate of potassium	205·0	135	Chloride of sodium .	41·2	108·4
Acetate of sodium .	209·0	124·4	Phosphate of sodium (dried)	112·6	106·6
Nitrate of sodium .	224·8	121			
Chloride of strontium .	117·5	117·8	Carbonate of sodium .	48·5	104·6
Nitrate of potassium .	335·1	115·9	Chloride of barium .	60·1	104·4
Chloride of ammonium	88·9	114·2			

(For Legrand's determinations of the boiling points of weaker solutions of these and some other salts, and for the similar experiments of Griffiths and Faraday, see Gmelin's *Handbook*, i. 269, 270.)

Very contradictory opinions have been maintained by different observers with regard to the temperature of the vapour which issues from boiling saline solutions. It has been said, on the one hand, to be the same as that of pure water boiling under the same pressure; and, on the other hand, to be equal to that of the highest stratum of the solution. According to the recent experiments of Magnus (Pogg. Ann. cxii. 408), the latter statement appears to be nearest the truth. These experiments prove decisively that the vapour of boiling solutions is hotter than that of pure water, and that its temperature rises as the solutions become more concentrated, and therefore boil at higher temperatures; nevertheless, the vapour was always found a little colder than the mass of the boiling solution, and the difference was greater at high temperatures than it was at low ones.

Relations between the Boiling Point of substances and their Chemical Composition.—Many attempts have been made to trace some connection between the boiling points of different liquids and their chemical composition. The most extensive and important series of observations that have been made upon this point are due to Kopp (Ann. Ch. Pharm. xcvi. 2, 330; xcviii. 267, 367; Phil. Trans. 1860, 257). The principal conclusions deducible from these investigations are as follows:—

1. Analogous compounds, presenting the same difference of composition, very frequently differ by the same amount in their boiling points, or the interval between their boiling points is proportional to their difference of composition. A compound containing xC more or less than another of analogous function, generally boils at a

Digitized by Google

temperature $x \times 29$ degrees higher or lower than the latter, and if it contains xH more or less it commonly boils at $x \times 5$ degrees lower or higher. A particular instance of the application of this rule is to homologous compounds: in the homologous acids $C^nH^{2n}O^2$ (Acids, i. 50), and in the corresponding alcohols and compound ethers, the addition of CH^2 to the formula of a compound raises its boiling point on an average by 19°, agreeing with the above rule.

2. An acid, $C^nH^{2n}O^2$, boils at a temperature 40° higher than the alcohol, $C^nH^{2n+2}O$ (Alcohols, i. 97), the oxidation of which may give rise to the acid.

3. A compound ether (Ethers, ii. 512), $C^nH^{2n}O^2$, boils at a temperature 82° lower than the acid, $C^nH^{2n}O^2$, isomeric with it.

If we start from the boiling point of ethyl-alcohol, = 78°, these three propositions enable us to calculate the boiling points of a large number of organic substances, alcohols, acids, and compound ethers, represented by the above general formulæ. The following tables serve to show how far the boiling points thus calculated correspond with those actually observed.

Boiling Points of Alcohols, $C^nH^{2n+2}O$.

Name.	Formula.	Calculated Boiling Point.	Observed Boiling Point.
Methylic alcohol .	CH^4O	59°	Kane, 60°; Delffs, 60·5°; Kopp, 65°; Pierre, 66°; Dumas and Péligot, 66·5°.
Ethylic alcohol .	C^2H^6O	78	Dumas and Boullay, 76°; Gay-Lussac, Pierre, Kopp, Delffs, Andrews, 78°.
Tritylic alcohol .	C^3H^8O	97	Chancel, 96°.
Tetrylic alcohol .	$C^4H^{10}O$	116	Wurtz, 109°.
Amylic alcohol .	$C^5H^{12}O$	135	Pasteur, 127°—129°; Cahours, Pierre, Kopp, Delffs, 132°; Rieckher, 136°.
Hexylic alcohol .	$C^6H^{14}O$	154	Faget, 148°—154°.
Heptylic alcohol .	$C^7H^{16}O$	173	Städeler, 177°—177·5°.
Cetylic alcohol .	$C^{16}H^{34}O$	344	Favre and Silbermann, 366°?

Boiling Points of Acids, $C^nH^{2n}O^2$.

Name.	Formula	Calculated Boiling Point.	Observed Boiling Point.
Formic acid . .	CH^2O^2	99°	Liebig, 99°; Bineau, Favre and Silbermann, 100°; Kopp, 105°.
Acetic acid . .	$C^2H^4O^2$	118	Delffs, 116°; Kopp, 117°; Sébille-Auger, 119°; Dumas, 120°.
Propionic acid .	$C^3H^6O^2$	137	Dumas, Malaguti, and Leblanc, about 140°; Limpricht, Kopp, 142°.
Butyric acid . .	$C^4H^8O^2$	156	Kopp, Delffs, 156°; Pierre, 163°; Pelouze and Gélis, about 164°.
Valeric acid . .	$C^5H^{10}O^2$	175	Dumas and Stas, Delffs, 175°; Kopp, 176°.
Caproic acid . .	$C^6H^{12}O^2$	194	Brazier and Gossleth, Wurtz, 198°; Fehling, 202°—209°.
Œnanthylic acid .	$C^7H^{14}O^2$	213	Städeler, 218°.
Caprylic acid . .	$C^8H^{16}O^2$	232	Fehling, 236°; Perrot, 238°.
Pelargonic acid .	$C^9H^{18}O^2$	251	Perrot, 225°; Cahours, 260°.

In other groups of compounds, a difference of CH^2 in the composition of analogous substances corresponds frequently to a nearly constant difference of boiling point: but this difference sometimes amounts to more than 19 degrees, and sometimes to less. For instance, in the series of hydrocarbons C^nH^{n-6}, homologous with benzene, C^6H^6, a difference of CH^2 in composition corresponds to an average difference of about 24° in boiling point; in the series of alcohol-radicles (or hydrides) C^nH^{2n+2}, homologous with ethyl, C^2H^{10}, (or marsh-gas, CH^4) the difference of boiling point corresponding to the same difference of composition, is also nearly 24°; in the series of acetones $C^nH^{2n}O$, it is about 22°. On the other hand, the difference of boiling point, corresponding to a difference of CH^2 in composition, is less than 19° in the anhydrides

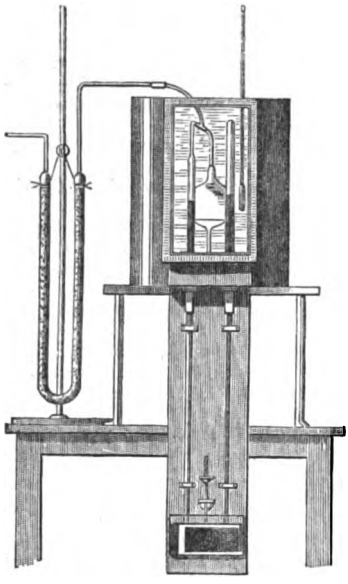
Boiling Points of Compound Ethers, $C^nH^{2n}O^2$.

Name.	Formula.	Calculated Boiling Point.	Observed Boiling Point.
Formate of methyl .	$C^2H^4O^2$	36°	Kopp, Andrews, 33°; Liebig, 36°—38°.
Acetate of methyl . / Formate of ethyl .	$C^3H^6O^2$	55	Andrews, 55°; Kopp, 56°; Dumas and Péligot, 58°. / Liebig, Delffs, 53°; Kopp, 55°; Löwig, 56°.
Acetate of ethyl . .	$C^4H^8O^2$	74	Dumas and Boullay, Pierre, Kopp, Delffs, 74°.
Butyrate of methyl / Acetate of trityl . / Formate of tetryl . / Propionate of ethyl	$C^5H^{10}O^2$	93	Favre and Silbermann, Delffs, 93°; Kopp, 95°; Pierre, 102°. / Berthelot, about 90°. / Wurtz, about 100°. / Kopp, 96°—98°; Limpricht and Uslar, 101°.
Valerate of methyl. / Butyrate of ethyl . / Acetate of tetryl . / Formate of amyl .	$C^6H^{12}O^2$	112	Kopp, 114°—115°. / Pelouze, 110°; Delffs, 113°; Kopp, 115°; Pierre, 119°. / Wurtz, 114°. / Delffs, 114°; Kopp, about 116°.
Valerate of ethyl . / Butyrate of trityl . / Acetate of amyl .	$C^7H^{14}O^2$	131	Delffs, 132; Otto, Kopp, Berthelot, 133°—134°. / Berthelot, about 130°. / Cahours, 125°; Kopp, Delffs, 133°.
Caproate of ethyl . / Propionate of amyl	$C^8H^{16}O^2$	150	Lerch, 120°; Fehling, 162°. / Wrightson, about 155°.
Butyrate of amyl . .	$C^9H^{18}O^2$	169	Delffs, 173°—176°.
Valerate of amyl . / Acetate of capryl .	$C^{10}H^{20}O^2$	188	Kopp, 188; Balard, about 196°. / Dachauer, 191—192°; Bouis, 193°.
Pelargonate of ethyl / Caproate of amyl .	$C^{11}H^{22}O^2$	207	Cahours, 216°—218; Delffs, 224°. / Brazier and Gossleth, 211°.
Laurostearate of ethyl	$C^{14}H^{28}O^2$	264	Görgey, 264°; Delffs, 269°.

$C^{2n}H^{4n-2}O^3$, homologous with acetic anhydride, $C^4H^6O^3$ (namely, about 12·5°); in the ethers of the acids $C^nH^{2n-2}O^4$, homologous with oxalic acid, $C^2H^2O^4$ (namely, about 14°); also in the carbonates, sulphocyanates and borates of the alcohol-radicles C^nH^{2n+1}.

These results seem to show that, as a rule, the greater the quantity of oxygen contained in any series of compounds, the smaller is the effect on the boiling point of a difference of composition amounting to CH^2.

In the chlorides, bromides and iodides of the alcohol-radicles C^nH^{2n+1}, a difference in composition of CH^2 causes a difference in boiling point of from 24 to 31 degrees; in the corresponding sulphides and sulphydrates (mercaptans) the difference also considerably exceeds 19°.



Measurement of the Tension of Vapours.—The various methods that have been employed for measuring the maximum tension of vapours at different temperatures, depend upon principles already explained. We have here to describe briefly the manner in which these principles were put in practice, and to state the most important results obtained.

The tension of vapours at temperatures below the ordinary boiling points of the corresponding liquids, and therefore at pressures less than that of the atmosphere, have been measured by determining the depression of the mercury column of a barometer produced by the saturated vapours at known temperatures. *Fig.* 543 represents the apparatus employed by Regnault (*Relation des Expériences*, &c. p. 489) in his principal series of experiments made by this method. The liquid whose vapour is to be examined is contained in a small bulb almost completely filled by it, and hermetically sealed without any trace of air. This bulb is introduced into a glass globe, the neck of which is then drawn out, bent at a right angle, and cemented into a narrow T-tube of copper, the other branches of which communicate, one of them through a drying tube containing pumice-stone and sulphuric acid, with an air-pump, the other, by a capillary tube, with the top of a wide glass tube open below and dipping into mercury. This last tube forms the barometer, the depressions of which are observed; its upper part

Digitized by Google

is inside a metal water-bath, one face of which is formed by a sheet of plate glass, and in which are also contained the upper part of an ordinary barometer, to serve as a standard of comparison, and the glass globe spoken of above; this, as shown in the figure, rests on a metal ring carried by a support rising from the bottom of the bath. Previous to beginning the experiments, the inside of the glass globe and of the tubes communicating with it is rendered absolutely dry by repeatedly pumping out the air, and each time allowing it to be filled again by air dried by passing through the sulphuric acid drying tube. Then, by bringing a piece of hot charcoal near the outside of the globe, the bulb containing the liquid is burst, and the experiments are proceeded with by observing simultaneously the temperature of the bath in which the globe is immersed, and the difference in height of the two barometers.

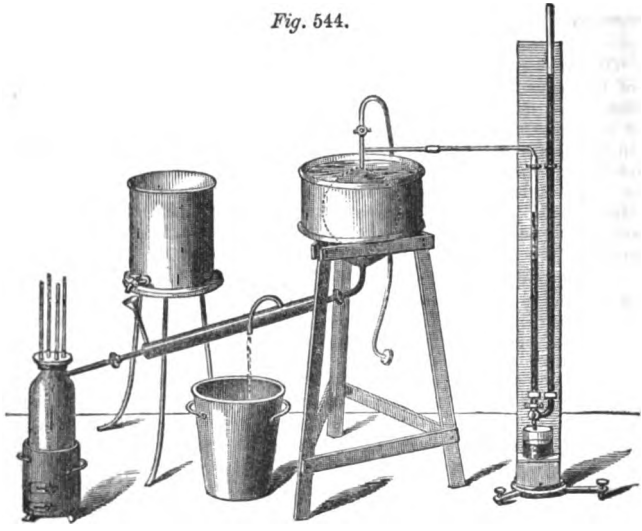


Fig. 543.

The same apparatus, slightly modified, served for the determination of the tension of vapours in presence of air or other gases.

For the determination of the tension of the vapour of water at higher temperatures, Regnault (*ibid.* p. 515) employed the apparatus represented in *fig.* 544, an apparatus which enabled him to measure the pressure under which water boiled at various temperatures (see p. 83). The apparatus consists of a copper retort, containing the water to be experimented upon, and communicating, through a tube surrounded by cold water (whereby the steam produced is condensed and whence it continually flows back as water into the retort), with a copper globe of 24 litres capacity. This globe is connected with a manometer which indicates the pressure inside the whole apparatus and

Fig. 544.

also with a branch tube by means of which air can be withdrawn from or forced into the apparatus, so as to bring the pressure to the required amount. The temperature of the boiling water in the retort is indicated by four thermometers, two of which dip into the water, and two into the steam. In order to prevent any alteration in the capacities of the bulbs of the thermometers, resulting from the pressure of the vapour upon them, they are enclosed in iron tubes, closed at the bottom and containing mercury.

The following table gives the results obtained at intervals of five degrees between

Digitized by Google

− 32° and + 230°. (For tables of the tensions of water-vapour at each degree centigrade between these limits, and at each tenth of a degree between −10° and +35° and between 85° and 101°, see Regnault, *loc. cit.* pp. 624–633.)

Maximum Tension of Water-vapour between −32° *and* +230°. (Regnault.)

Determinations of the tension of water-vapour up to 111 degrees have also been made by Magnus (Pogg. Ann. lxi. 225) by a method essentially similar to the first of those above described. His results agree closely with those of Regnault. (For the older determinations of the pressure of steam at high temperatures by Arago and Dulong, see Gmelin's *Handbook*, i. 262.)

The following table, by Fairbairn and Tate (Phil. Trans. 1860, p. 220), gives the temperatures at which water is completely converted into saturated steam under various pressures, together with the volume of steam formed under these circumstances compared with that of the water from which it is produced.

Pressure, Temperature, and Volume of Saturated Steam.

It was supposed by Dalton that the tension of the vapours of all liquids is the sam at temperatures equally distant from their respective boiling points. The observation from which the above tables are constructed show that this rule is not strictly true, bu is nearly so in most cases for small intervals of temperature above or below the boilin points: hence, in order to correct boiling point observations for the variations o atmospheric pressure, it may be assumed without sensible error that a difference o pressure equal to 2·7 millimetres of mercury causes a difference in the boiling point of all liquids, equal to that which it produces in the case of water,—namely, 0·1° C (see pp. 85 and 92.)

Tension of the Vapours of Mixed Liquids and of Saline Solutions.—Regnault' experiments on the tension of the vapour of mixed liquids prove that: (1) when tw liquids exert no solvent action upon each other, as *water* and *sulphide of carbon*, wate and *bichloride of carbon* (CCl^4), or water and *benzene*, the tension of the vapour whic rises from a mixture of them is very nearly equal to the sum of the tensions of the tw separate liquids at the same temperature; (2) with water and ether, which dissolv each other to some extent, but not in all proportions, the tension of the vapour of th mixture is much less than the sum of tensions of the separate liquids, being scarcel equal to that of ether only; (3) when the two liquids dissolve each other in all pr portions, as ether and sulphide of carbon, benzene and alcohol, water and alcohol, th tension of the vapour of the mixed liquid is intermediate between the tensions of th separate liquids.

The tension of the vapour of saline solutions has been examined by Regnault ar by Wüllner (Jahresber. 1858, 42–47; 1860, 47–49). Regnault's experiments we

Digitized by Google

nade by means of the apparatus represented in *fig.* 543, p. 92; Wüllner employed a differently arranged apparatus, but one which depended on essentially the same principles. It results from these investigations that the tension of the vapour of a solution is less than that of the vapour of pure water at the same temperature, and that in the case of efflorescent salts and of salts that are permanent in the air, the diminution of the tension of the vapour emitted by the solution is exactly proportional to the quantity of salt dissolved in a constant weight of water, but in the case of deliquescent salts it is proportional to the quantity of hydrated salt dissolved: *e. g.*, for a solution of potash, to the quantity of $KHO.2H^2O$; for a solution of soda, to the quantity of $NaHO.1\frac{1}{2}H^2O$; for a solution of chloride of calcium, to the quantity of $CaCl^2.6H^2O$. The absolute amount of diminution of tension depends on the temperature, and becomes greater as the temperature rises.

Tension of Vapours in an unevenly heated space.—In an enclosed space, the temperature of which is different at different parts, the vapour of a liquid can assume a state of statical equilibrium only when its tension is equal to the maximum tension corresponding to the temperature of the coldest part of the space. If the vapour has, to begin with, a greater tension than this, liquefaction will take place in the coldest part, since the pressure is greater than that which the vapour can support at the temperature of this part, and this process will continue until the tension throughout the whole space is reduced to the point already stated. It is upon this principle that the process of distillation, and the action of the condenser of the steam engine, depend.

Complete Vaporisation of Liquids under great pressures.—When the temperature of a liquid is raised sufficiently high, vaporisation occurs under the highest pressure to which the substance can be subjected. Alcohol, ether, or rock-oil, enclosed in a tube of strong glass or iron, is completely converted into vapour only when the space not occupied by the liquid is somewhat greater than the volume of the liquid itself. With rock-oil the empty space may be somewhat smaller than with alcohol, and with ether still less. Alcohol when thus heated acquires increased mobility, expands to twice its original volume, and is then suddenly converted into vapour. This change takes place at 207° C. (404·6° Fah.), when the alcohol occupies just half the volume of the tube; if the tube is more than half filled with alcohol, it bursts when heated. A glass tube one-third filled with water becomes opaque when heated, and bursts after a few seconds. If this chemical action of the water on the glass be diminished by the addition of a little carbonate of soda, the transparency of the glass will be much less impaired; and if the space occupied by the water be $\frac{1}{4}$ of the whole tube, the liquid will be converted into vapour at about the temperature of melting zinc (Cagniard de la Tour).—If liquid carbonic anhydride sealed in a glass tube occupies $\frac{13}{30}$ of the volume of the tube at 0°, it neither increases nor diminishes in bulk when heated, because the increase of volume produced by heating is just compensated by the diminution caused by vaporisation. If it occupies $\frac{1}{2}$ of the space at 0°, its volume diminishes when it is heated, and increases when it is cooled, because the loss by evaporation preponderates over the expansion. If it takes up $\frac{2}{3}$ of the space, its volume increases by heat and contracts by cold, as in a thermometer; but at + 30° (86° Fah.) the whole is converted into vapour. The gas, which at 0° occupies the space above the liquid carbonic anhydride would, if condensed, yield $\frac{1}{12}$ of its volume of liquid acid; and that which is produced at + 30° would give $\frac{1}{3}$ ($\frac{1}{4}$? Gmelin) of its volume of liquid carbonic anhydride at 0°. (Thilorier.)

When chloride of ethyl was heated in a very thick sealed tube, the upper surface ceased to be distinctly marked at about 170°, and was replaced by an ill defined nebulous zone possessing no reflecting power; as the temperature rose, this zone increased in width in both directions, becoming at the same time more and more transparent. After a time, the liquid was entirely converted into vapour, and the tube became quite transparent and apparently empty. As the temperature fell, the same phenomena were reproduced in the opposite order (Drion, Ann. Ch. Phys. [3] lvi. 33). Similar appearances were observed on heating ether in a sealed tube to about 190°. According to Drion, the temperature at which ether is completely vaporised, in a space nearly three times its original volume, is 190·5°. The precise temperatures observed in these experiments are, however, of no real significance, unless they are accompanied by accurate determinations of the corresponding real volumes of the liquid and vapour.

It has been similarly observed by Andrews that when liquid carbonic anhydride was gradually heated to 31°, the surface of demarcation between the liquid and gas became fainter, lost its curvature, and at last disappeared. The space was then occupied by a homogeneous fluid, which exhibited, when the pressure was suddenly diminished, or the temperature slightly lowered, a peculiar appearance of moving or flickering striæ throughout its entire mass. At temperatures above 31° no apparent liquefaction of carbonic anhydride or separation into two distinct forms of matter could be effected,

Digitized by Google

even when a pressure of 300 or 400 atmospheres was applied. Nitrous oxide gave similar results. (Andrews, in Miller's *Chemical Physics*, ed. 1863, pp. 328, 329.)

Latent Heat of Vaporisation.—When heat is imparted to a volatile liquid, its effect is, at most temperatures, twofold. Part of it goes to increase the temperature of the liquid, and part to cause vaporisation. But when a liquid is boiling under constant pressure, however much heat is communicated to it, the whole of it is absorbed in producing the second of these effects only. Conversely, when heat is withdrawn from a saturated vapour, under a pressure which is maintained constant, the vapour is changed into a liquid, without alteration of temperature. The consumption of heat in vaporisation, without the production of a corresponding elevation of temperature, and its evolution during condensation, unaccompanied by a corresponding fall of temperature, were first observed by Black. These phenomena were described by him by saying that during the former process, a certain quantity of sensible heat became latent, and that this latent heat became sensible again during condensation. The quantity of heat that must be given to a liquid to convert it into vapour, or which must be withdrawn from a vapour to convert it into liquid, without causing change of temperature, is still spoken of as the latent heat of vaporisation.

The determination of this quantity is made by determining the specific heat of the substance for an interval of temperature within which it passes from the liquid to the vaporous state, or *vice versâ*, and is therefore in principle similar to the determination of the latent heat of fluidity (p. 77). The following table gives the number of units of heat which must be imparted to a unit of weight of various liquids at their respective boiling points, in order to convert them into vapours at the same temperatures. The letters F S in the third and sixth columns denote that the determinations were made by Favre and Silbermann (Ann. Chim. Phys. [3] xxxvii. 464–470); the letter A denotes determinations by Andrews (Chem. Soc. Qu. J. i. 27); and Rg, by Regnault.

The latent heat of vaporisation varies with the temperature at which the vapour formed; more heat is for instance required to convert a given quantity of water 50° into vapour of the same temperature than to produce the same change in water 100°. It was supposed by Watt that the latent heat of vaporisation diminished exactly at the same rate as the sensible heat increased, so that the sum of the two remained constant at all temperatures. But Regnault (*Relation des Expériences*, &c. pp. 635—728; also *Works of the Cavendish Society*, vol. i. p. 294) has shown that this is not the case. He finds that the total quantity of heat λ (expressed in heat-units) which a unit of weight of saturated aqueous vapour contains at the temperature $t°$ C exceeds the amount contained in the same weight of water at 0° by the quantity

$$\lambda = 606{\cdot}5 + 0{\cdot}305\,t.$$

If from this we subtract the quantity of heat which a unit of weight of water at contains, beyond that which is contained in the same weight of water at 0° (see Regnault's determinations of the specific heat of water at different temperatures, p. 34

Digitized by Google

we shall obtain the latent heat L of the vapour of water at the temperature $t°$. The values of λ and L for various temperatures are given in the next table, together with the tensions expressed in millimetres and atmospheres.

Latent Heat of Water-Vapour.

Temperature.	Tension.		λ	L
	mm.	atm.		
0° C.	4·60	0·006	606·5	606·5
50	91 98	1·121	621·7	571·6
100	760·00	1·000	637·0	536·5
150	3581·23	4·712	652·2	500·7
200	11688·96	15·380	667·5	464·3
230	20926·40	27·535	676·6	441·9

The following formulæ represent in like manner the results of Regnault's determinations (Mém. Acad. Sciences, xxvi. 881) of the total heats of vaporisation of several other substances at various temperatures:

Sulphide of carbon: $\lambda = 90·0 + 0·14601\,t - 0·0004123\,t^2$.
Ether: $\lambda = 94·0 + 0·4500\,t - 0·0005555\,t^2$.
Benzene: $\lambda = 109·0 + 0·2443\,t - 0·0001315\,t^2$.
Chloroform: $\lambda = 67·0 + 0·1375\,t$.
Perchloride of carbon (CCl^4): $\lambda = 52·0 + 0·1463\,t - 0·000172\,t^2$.
Acetone: $\lambda = 140·5 + 0·3664\,t - 0·000516\,t^2$.

The following table gives the total heats of vaporisation of some additional liquids at the temperatures at which they boil under the ordinary atmospheric pressure (*ibid.* 913):

Substance.	Boiling Point.	Total Heat of Vaporisation.	Substance.	Boiling Point.	Total Heat of Vaporisation.
Alcohol . . .	78·26°	265·52	Bromine . . .	60°	50·95

Oil of turpentine . .	159·15	139·15	Trichloride of phosphorus .	73·80	67·24
Petrolene . . .	. .	194·87			
Chloride of ethyl . .	12·50	97·70	Acetate of ethyl .	74	154·49
Iodide of ethyl . .	71	58·95			

Regnault finds, as the result of direct experiments (*ibid.* 903), "that the total heat of vaporisation of a liquid in a current of gas is equal to that which the same liquid absorbs when it boils in an atmosphere formed by its own vapour, and exerting an elastic force equal to that actually acquired by the vapour of the liquid in the current of gas."

Cold produced by Vaporisation. Liquefaction of Gases.—When the evaporation of a liquid is hastened by reducing the pressure upon it and continually removing the vapour which forms, or by exposing a large surface and rapidly renewing the atmosphere in contact with it, the consequent absorption of heat is such, in the case of the more volatile liquids, as to produce a very considerable fall of temperature. Water, for instance, may be frozen by placing it under the exhausted receiver of an air-pump near a vessel of strong sulphuric acid (Leslie). The rapid volatilisation of more volatile liquids produces still more striking results, and in fact constitutes the most effectual means known of producing extremely low temperatures.

By causing a rapid stream of dry air from the bellows of a glass-blowers' lamp to bubble by several tubes at once through about 200 grammes of ether, Loir and Drion (Bull. Soc. Chim. Paris, i. 184; Séance du 22 Juin, 1860) succeeded in reducing the temperature of the liquid to −34° in 4 or 5 minutes, and maintaining this temperature very nearly constant for at least 15 or 20 minutes. At this temperature considerable quantities of *cyanogen* can be condensed at the atmospheric pressure. The condensation of this gas begins under these circumstances at about −22°; by blowing gently on the surface of the condensed liquid with a common pair of bellows it is immediately caused to solidify. By similar means, *sulphurous anhydride* is easily liquefied. *Chlorine* does not condense under the common pressure at −34°, but by using liquid

Digitized by Google

sulphurous anhydride in place of ether, a temperature of $-50°$ can be produced, and this is amply sufficient for the liquefaction of both chlorine and *ammonia*. Lastly, by evaporating liquid ammonia (which boils in the air at $-35·7°$) in an exhausted receiver over sulphuric acid, they attained the temperature of about $-87°$, at which point the ammonia solidified, and *carbonic anhydride* condensed to a liquid at the common atmospheric pressure.

An apparatus for the liquefaction of ammonia, to be used for refrigeration, has been described by Regnault (Mém. Acad. Sciences, xxvi. 609), and a very simple contrivance for the same purpose was exhibited by Carré at the International Exhibition in London in 1862. (For a description and figure of the last apparatus, see Miller's *Chemical Physics*, ed. 1863, p. 298, footnote.)

Several gases can be liquefied by increased pressure alone, without reducing their temperature below that of the atmosphere. The necessary pressure can often be attained by evolving the gas in an enclosed space (as in a sealed glass tube); under these circumstances, the elastic force continues to increase until the point of maximum tension is reached, and then liquefaction occurs. In this way, carbonic anhydride may be liquefied by its own pressure when it is evolved from acid carbonate of sodium and diluted sulphuric acid in a strong wrought iron bottle connected with a wrought iron receiver. When the liquid carbonic anhydride thus produced is allowed to escape in a fine stream into the air, part of it is immediately vaporised, and the consequent absorption of heat is sufficient to cause the remainder to condense to a white, crystalline solid, like snow. The principle of this method was first put in practice by Faraday in experiments on the small scale; an apparatus in which considerable quantities of liquid carbonic anhydride could be thus prepared was first devised and constructed by Thilorier.

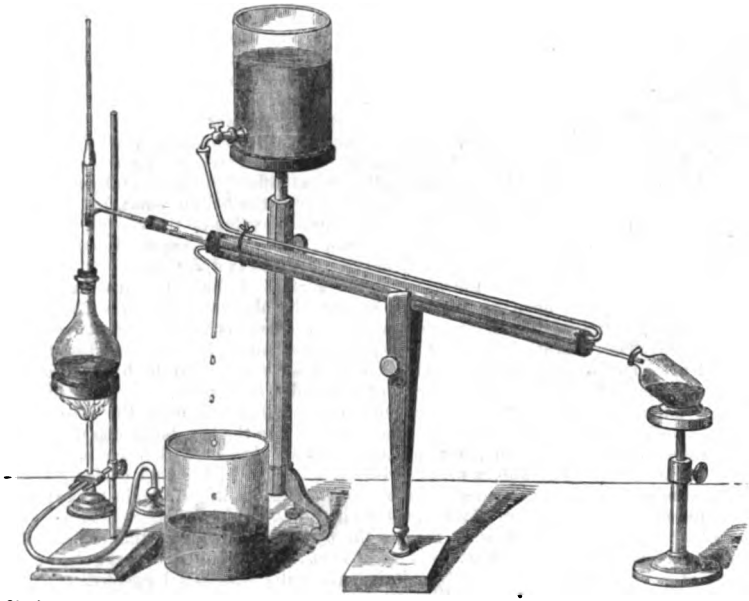
The pressure necessary for the liquefaction of gases may also be produced by compressing them by means of a force-pump, as in Natterer's apparatus for the liquefaction of nitrous oxide.

By the evaporation of gases, condensed by any of the processes above indicated, the lowest temperatures yet attained can be produced, the greatest degree of cold hitherto recorded being $-140°$, the temperature, according to Natterer, of a mixture of liquid nitrous oxide and bisulphide of carbon evaporating *in vacuo*.

Still more powerful means of liquefaction than those already mentioned, were employed by Faraday in his later experiments on this subject (Phil. Trans. 1845, p. 170), and he thereby succeeded in reducing to the liquid state all known gases, with the exception of oxygen, hydrogen, nitrogen, nitric oxide, carbonic oxide, and marsh-gas, —and in solidifying the greater number of them. The method adopted was to subject the gases to the joint action of powerful mechanical pressure and extreme cold. The first object was attained by the successive action of two air-pumps, the first having a piston one inch in diameter, the second only half an inch. The first produced a pressure of about 20 atmospheres, the second increased it to upwards of 50. The tubes into which the gas thus condensed was made to pass were of green bottle-glass, from $\frac{1}{8}$ to $\frac{1}{4}$ of an inch in external diameter, and had a curvature in one portion of their length adapted for immersion in a freezing mixture. The mixture employed consisted of solid carbonic anhydride and ether. The cold produced by it amounted to $-76·6°$ in the open air, and to $-110°$ under the exhausted receiver of the air-pump.

Many gases, when subjected to this extreme degree of cold, were liquefied without the use of the condensing apparatus: this was the case with chlorine, cyanogen, ammonia, sulphuretted hydrogen, arseniuretted hydrogen, hydriodic acid, hydrobromic acid, carbonic anhydride, ethylene, nitrous oxide, and oxide of chlorine. Fluoride of silicon liquefied at a pressure of 9 atmospheres. The following were solidified when subjected to the action of the carbonic anhydride bath *in vacuo:* hydriodic acid, hydrobromic acid, sulphurous anhydride, sulphuretted hydrogen, carbonic anhydride, oxide of chlorine, cyanogen, ammonia, and nitrous oxide. The following gases did not solidify, even at the lowest temperature that could be obtained: ethylene, fluoride of silicon, fluoride of boron, phosphoretted hydrogen, hydrochloric acid, and arseniuretted hydrogen. The six gases mentioned at the commencement of the preceding paragraph showed no signs of liquefaction when cooled by the carbonic anhydride bath *in vacuo:* hydrogen and oxygen at 27 atmospheres, nitrogen and nitric oxide at 50, carbonic oxide at 40, and marsh-gas at 32 atmospheres.

Andrews has since succeeded in exposing these gases to still greater pressures, but without producing liquefaction, although a bath of ether and solid carbonic anhydride was used; air was reduced to $\frac{1}{675}$ of its bulk, oxygen to $\frac{1}{554}$, hydrogen to $\frac{1}{506}$, carbonic oxide to $\frac{1}{278}$, and nitric oxide to $\frac{1}{680}$ of its original volume. Hydrogen and carbonic oxide departed less from Boyle's law than oxygen and nitric oxide.



Distillation. — One of the processes most frequently resorted to by the chemist for the purpose of separating different substances is to expose the mixture containing

Digitized by Google

them to a temperature at which the constituent it is wished to isolate rises in vapour, while the others remain still solid or liquid. The ordinary methods of performing this operation of distillation, and the apparatus commonly employed are too familiar to every chemist for it to be necessary to describe them here in detail. (For a full description of the process and the modifications that become desirable in particular cases, the reader is referred to *A Handbook of Chemical Manipulation*, by C. Greville Williams, London, 1857, pp. 202–244.)

When the liquid submitted to distillation is a mixture of two or more substances of unequal volatility, the vapour formed when ebullition begins generally contains a larger percentage of the most volatile constituent than the liquid remaining in the retort. Hence, the composition of the liquid alters as the distillation continues, and its boiling point rises accordingly. On the other hand, if the boiling point of a liquid remains constant during distillation, it is usually an indication that its composition is unaltered by the process, and therefore that the composition of the distillate also continues the same throughout. The boiling point of a liquid becomes therefore a very useful indication of the uniform or varying nature of the products of its distillation, and by collecting apart the portions which pass over at different temperatures, a mixture of different liquids may often be to a great extent resolved into its constituents. It seldom happens, however, except with a mixture of two liquids whose boiling points are very distant from each other, that a single operation of this kind gives either constituent in a state of purity. This is especially the case when the distillation is performed in a retort or other vessel which allows the vapour to pass to the condenser almost immediately after its formation. Under these circumstances, the distillate obtained at any period of the operation is almost identical in composition with the vapour that is rising from the liquid, and therefore contains a certain quantity of every constituent of the liquid that produces vapour of sensible tension at the temperature at which ebullition is going on. Hence, in order to effect any great amount of separation in this manner, the distillate must be collected in separate fractions, each of them corresponding to a definite interval of temperature; each fraction must then be fractionally distilled by itself, in the same way as the original liquid, the products which pass over between the same temperatures on the second distillation of the first fractions being collected together; and this process must be repeated as long as any further separation into

Fig. 545.

distinct constituents can be effected. These numerous re-distillations may often be considerably curtailed by using, instead of a retort, a flask fitted with a rather wide branched tube, of the form shown in *fig.* 545. The thermometer is inserted into the upright limb of the branched tube, and is so adjusted in the cork or piece of india-rubber tube which holds it in its place, that the top of the bulb is just below the opening of

Digitized by Google

the side branch by which the vapour passes to the condenser. In an apparatus t
arranged, the vapour rising from the liquid comes in contact with a considerable surf
of glass cooled by contact with the air, before it is able to leave the distilling vessel:
consequence is that, in proportion as it rises above the surface of the boiling liquid
becomes more and more completely freed from its less volatile constituents; and the
pour which ultimately reaches the condenser, at any stage of the operation, is identi
with the most volatile portions that would be obtained by the repeated fractional dis
lation of the liquid resulting from the complete condensation of the vapour existing in
flask at the time. In fact, one distillation made in this way is equivalent to several m
in a retort; nevertheless, this method is not always applicable, since the temperature
the boiling liquid requires to be always considerably higher than that of the liquid wh
is actually distilling, otherwise the whole of the vapour would be condensed before rea
ing the exit tube—and this would sometimes cause chemical alteration of the substan

The composition of the distillate which a liquid yields at any period of its distillat
does not depend solely upon the tension of the vapours of its several constituents at
temperature of ebullition; it is greatly influenced also by their relative proportio
and by the densities of their vapours. In distilling a volatile liquid containing a sm
quantity of a less volatile one (for instance, benzene containing a little water), it m
very often be noticed that the whole of the less volatile constituent is contained in
first few drops of the distillate. This is because the latter substance produces vap
of whatever tension corresponds to the temperature of ebullition of the mass of
liquid, just as a larger quantity of it would do; this vapour diffuses itself through th
of the more volatile constituent and is carried forward with it into the condenser;
further quantity of the less volatile vapour is then formed, and the process contin
thus until the whole of the less volatile liquid has been volatilised, although the te
perature may not have approached within many degrees of its boiling point.

The influence of the vapour-densities of the several constituents of a mixed liqu
upon the rapidity with which they respectively distil, has been specially pointed out
Wanklyn (Proc. Roy. Soc. xii. 534) and by Berthelot (Compt. rend. lvii. 430). Le
ing out of consideration the influence of the adhesion of the ingredients for each oth
the quantity of each ingredient which distils may be found by multiplying its tensi
at the boiling point of the mixture by its vapour-density. Hence, the liquid wh
vapour has the highest tension will not necessarily distil the quickest: what the oth
liquids want in tension, they may make up by the greater density of the vapours whi
they give off. Wanklyn gives the following experiment in illustration of this effe
18 grms. of methylic alcohol—boiling point 66°, vapour-density 1·107—was mixed wi
17 grms. of iodide of ethyl—boiling point 72°, vapour-density 5·397—and the mixtu
was distilled until rather more than one-third had passed over. The distillate (14
grms.) consisted of 6·0 grms. of methylic alcohol and 8·7 grms. of iodide of eth
showing that the less volatile constituent, owing to its greater density of vapour, h
distilled most quickly. When the vapour-densities and tensions are inversely propo
tional, the mixture must distil over unchanged. This influence of vapour-density go
a great way to explain why homologous bodies are so difficult to separate by fraction
distillation. The more complex the formula the higher the boiling point, but also t
higher the vapour-density, and therefore the greater the value of the vapour. It al
explains why oils, &c. distil so readily in steam; for aqueous vapour is one of th
lightest, while oily vapours are generally heavy. (Wanklyn, *loc. cit.*)

The action of the sun upon the water at the surface of the earth causes a natur
process of distillation upon an enormous scale to be always going on. The wat
evaporated from the earth's surface rises in the atmosphere as vapour, and being afte
wards deprived of its heat of vaporisation—partly by radiation into space, and partly b
contact with mountain summits, or with the cold air existing at high elevations
returns to the earth in the various forms of dew, mist, rain, snow, hail, &c. In th
way an immense quantity of water is being continually lifted from the sea-level,
large proportion of which does not fall again directly into the sea, but, being deposite
on elevated portions of the land, becomes the inexhaustible source whence streams an
rivers are supplied. The watery vapour which reaches the higher and colder regio
of the atmosphere, is there condensed into snow. This, as it falls again towards th
earth, returns to the condition of water, if the air through which it passes is sufficientl
warm to liquefy it; but part of it reaches the earth unmelted, and that which fall
upon regions whose mean temperature is below zero, accumulates to form the enormou
masses of ice known as glaciers. Now it is universally admitted by geologists that
at an epoch by no means (geologically) remote, extensive glaciers existed where non
have been known within historic times, and that glaciers which still exist had then
very much greater extent. In order to account for the former existence of so muc
larger a quantity of ice at the surface of the earth than that which is now to be found
it has often been supposed that, at the period when this occurred, the mean tempera

Digitized by Google

ture of the earth was considerably lower than at present. But, as Tyndall has pointed out (*Heat considered as a Mode of Motion*, pp. 192, 193), even admitting such to have been the case, the observed result would not have followed. If cold is necessary to condense the vapour of water into ice, heat is no less needed for the first production of the vapour. Hence the condition of the earth which is in reality indicated by the vast development of glaciers in former ages, is one in which the process of distillation went on more rapidly. These considerations have been recently carried further by Frankland. He has shown, by the comparison of well-established data, that the height of the line of perpetual snow above the sea-level at different parts of the earth, depends, not only upon the temperature, but also upon the amount of atmospheric precipitation which takes place; and he concludes, from Tyndall's experiments on the absorption and radiation of heat by aqueous vapour (see RADIATION OF HEAT), that the condensation of the vapour contained in the atmosphere takes place chiefly by the direct radiation of its heat of vaporisation into space. If this conclusion is correct, condensation must have occurred with nearly equal readiness at all stages of the earth's history, and all that was therefore necessary to cause a greater atmospheric precipitation in past times, was a more rapid supply of aqueous vapour. Hence, according to Frankland, the glacial epoch of the geologists is an indication of a higher mean temperature of the earth's surface in former ages, and not of a lower temperature. The climatological conditions of this epoch he considers to have been a necessary consequence of the continuous cooling of the earth's crust from the high temperature which it is admitted to have had at a still earlier era to that which it has at present. In the earlier ages alluded to, the temperature of the earth is supposed to have been such that a great part of the waters of our present ocean must have existed as vapour; and notwithstanding that rapid condensation of this vapour must have occurred, the surface of the earth was too hot to allow the precipitated water to accumulate as ice. But as the cooling progressed, the temperature of the land would fall more quickly than that of the ocean; hence a period would arrive when the former would be so far cooled that ice could accumulate upon it, while the temperature of the water still remained such that evaporation, and consequently condensation, went on much more rapidly than at present. It is during this period that, according to Frankland, the glacial epoch occurred. Its cessation he attributes to the further action of the same cause as that which produced it; namely, to the progressive cooling of the earth, which has now arrived at such a point that evaporation no longer takes place with sufficient rapidity to supply the materials required for the formation of the enormous glaciers of former ages. It is impossible to discuss here the cause of the former high temperature of the earth's surface, indicated by the tropical fauna and flora which preceded the glacial epoch, and, according to Frankland, by the glacial epoch itself; but it has been proved by Thomson that, for ages long anterior to either of the periods referred to, the internal heat of the earth can have produced no sensible effect upon the climate of the surface.

Just as in the process of distillation, as carried on in the laboratory, there is a transference of heat from the retort to the condenser, and consequently a constant tendency to the approximation of their temperatures: so one of the effects of the great natural process of distillation is the partial equalisation of the temperature of different parts of the earth's surface, and of the different strata of the atmosphere.

Various instruments and processes, mostly depending on principles already explained in this article, have been proposed for measuring the quantity of aqueous vapour existing in the air at any given time. A full description of all the most important of them will be found in the article HYGROMETER.

SUBLIMATION.—When, during the distillation of a volatile substance, the temperature of the receiver is kept so low that the vapour which enters it passes at once into the solid state, without previous liquefaction, the process is called sublimation, and the product a sublimate. This process is often resorted to for the purification of substances which volatilise rapidly at temperatures below their melting points.

Changes of Physical Structure.—Some solid substances are capable of existing under two or more forms distinguished from each other by differences of specific gravity, hardness, crystalline form, fusibility, optical and electrical properties, &c. Carbon, for instance, exists as diamond, graphite, and charcoal, as well as in other secondary modifications; phosphorus occurs either as an easily fusible, translucent, yellowish, crystalline substance, or as a much less fusible, opaque, amorphous body of a brick-red colour; and so for many other substances, simple and compound. It thus often happens that the different modifications of the same substance differ more in their physical properties, than other substances do which are chemically distinct; and the passage from one modification to another, though not amounting to a change of state of aggregation, may be considered as a phenomenon of the same class as such changes. Accordingly, it has been found, in all cases in which this point has been investigated, that the passage of a solid body from one modification to another, is attended either

Digitized by Google

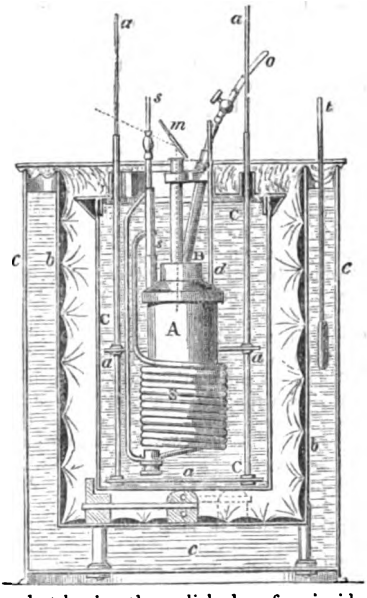
with development or with absorption of heat. The experiments which have been ma on this subject are not numerous enough to enable any general conclusions to be dra from them with great certainty, but they appear to indicate that development of he usually attends the passage from a vitreous or amorphous condition to a crystalli condition, and consequently that the opposite change is accompanied by absorption of hea

The following are examples of transformations of the kind under consideration :- 1. If melted sugar be allowed to cool to about 38°, and then, while it is still soft a viscid, be rapidly and frequently extended and doubled up, till at last it consists threads, as in drawn sugar, the temperature of the mass quickly rises so as to becom insupportable to the hand. After this liberation of heat, the sugar on again coolin is no longer a glass, but consists of minute crystalline grains and has a pearly lustr The same change may occur in a gradual manner, as when a clear stick of barley-sug becomes white and opaque in the atmosphere (Graham, *Elements of Chemistry*, 2n ed. i. 45).—2. When the soft vitreous sulphur, obtained by pouring sulphur melted 180° or 200° into cold water, is gradually heated in an air-bath of which the temper ture is about 98°, the temperature of the sulphur, as soon as it reaches 93°, ris suddenly to 110°, and it then passes immediately into the hard crystalline state whic it would have assumed gradually at the ordinary temperature (Regnault, Ann. C Phys. [3] i. 205). The prismatic crystals of sulphur obtained by fusion have bee long known to pass gradually into octahedral crystals. The same change takes pla much more quickly when the crystals are agitated, or when they are put in conta with sulphide of carbon, even if this liquid is already saturated with sulphu Mitscherlich found that the rapid transformation of prismatic into octahedral su phur which occurs under these circumstances was attended by the evolution of quantity of heat sufficient to raise the temperature of the sulphur employed by 12°, which, taking into account the specific heat of sulphur, amounted to 2·27 units of hea per gramme of sulphur (*ibid.* xlvi. 124). Favre, who has estimated by an indire process (Jahresber. 1853, p. 29) the heat evolved in the transformation of one variet of sulphur into another, finds that the quantity of heat liberated, when one equivalen (16 parts) of ordinary sulphur is converted into the modification insoluble in sulphid of carbon, amounts to 3102 units, and that the conversion into the same modificatio of one equivalent of soft vitreous sulphur, evolves 3804 units of heat.—3. Seleniun when completely melted and then rapidly cooled, constitutes a black mass with brilliant surface and a fracture exactly resembling that of obsidian or of black glas When this is heated very gradually, a sudden rise of temperature to 200° or 230° take place as soon as the thermometer arrives at 96° or 97°. The selenium is afterwards a bluish grey colour, and has a distinctly metallic lustre. Its fracture, instead of bein vitreous, now shows a fine granular structure like that of grey cast iron. The hea evolved in the transformation is estimated by Regnault as sufficient to raise the tem perature of the selenium operated upon by more than 200 degrees (Ann. Ch. Phys [3] xlvi. 290).—4. According to Favre (*loc. cit.*), 28,246 units of heat are evolved whe one equivalent (31 parts) of common phosphorus is converted into red phosphorus.— 5. The transformation of 1 grm. of arragonite into calc-spar corresponds to the evolutio of 12·9 units of heat (Favre and Silbermann, Ann. Ch. Phys. [3] xxxvii. 435).— 6. Many amorphous minerals and artificially prepared metallic oxides become tem porarily incandescent when gently heated, and are then found to have become crystallin without having undergone any alteration in weight. Gadolinite (silicate of yttrium exhibits this behaviour in a remarkable degree. (For further examples of analogou changes, see Gmelin's *Handbook*, i. 104–107.)

The existence of ozone seems to prove that the same chemical substance may exis even in the gaseous state, in more than one modification, and analogy renders it pro bable that, when such is the case, the transformation of one modification into the othe is attended by calorimetric phenomena. Sulphur-vapour at temperatures only slightl above the boiling point of sulphur, and at 800° and upwards, is an instance of anothe kind of difference in the properties of one and the same gaseous substance, which un doubtedly depends on the quantity of heat present in it, although the heat needed t change the one modification into the other has not been measured.

4.—*Relations of Heat to Chemical Affinity.*

Whatever may be the real nature of that property of matter called chemica affinity, by virtue of which mutual alterations of composition occur when chemically dissimilar bodies are brought together under appropriate conditions, one most im portant fact is clearly established with regard to it; namely, that its manifestation are always accompanied by the production or annihilation of heat. Change of compo sition, or chemical action, and heat are mutually convertible: a given amount o chemical action will give rise to a certain definite amount of heat, which quantity o heat must be directly or indirectly expended, in order to reverse or undo the chemical



Digitized by Google

action that has produced it. The production of heat by chemical action, and the definite quantitative relation between the amount of heat evolved and the quantity of chemical action which takes place, are roughly indicated by the facts of our most familiar experience; thus, for instance, the only practically important method of producing heat artificially consists in changing the elements of wood and coal, together with atmospheric oxygen, into carbonic anhydride and water, and every one knows that the heat which can be thus obtained from a given quantity of coal is limited and is at least approximately always the same.

The accurate measurement of the quantity of heat produced by a given amount of chemical action is a problem of very great difficulty; chiefly because chemical changes very seldom take place alone, but are almost always accompanied by physical changes involving further calorimetric effects, each of which requires to be accurately measured and allowed for, before the effect due to the chemical action can be rightly estimated. Thus the ultimate result comes, in most cases, to be deduced from a great number of independent measurements, each of which is liable to a certain amount of error. It is therefore not surprising that the results of various experiments should differ to a comparatively great extent, and that some uncertainty should still exist as to the exact quantity of heat corresponding to even the simplest cases of chemical action.

Heat evolved in rapid Combustions.—The reactions in which the evolution of heat is most strikingly evident, are of course those which are accompanied by visible incandescence or combustion; and, accordingly, the earliest experiments on the heat of chemical action had reference solely to the heat disengaged in rapid combustions. Lavoisier and Laplace were the first investigators of this subject. Their experiments, made about 1780, consisted in ascertaining the quantity of ice which could be melted by burning in a current of air known weights of the substances examined. In 1814, Count Rumford made experiments of a similar kind by means of a water-calorimeter. His chief object was to ascertain the relative calorific values of the principal combustible substances in actual use as fuel, and from this point of view his results still possess considerable value, although they cannot lay claim to scientific accuracy. In order to counteract the influence of the air and other external objects upon the temperature of his calorimeter, or at least to reduce that influence to a minimum, Rumford began each experiment when the water of the calorimeter was as much colder than the surrounding air, as (he had found by preliminary trials) it would be hotter at the end of the experiment. In this way, the calorimeter gained heat from the air during the first half of each operation, and lost an almost exactly equal quantity during the second half, so that the total effect was almost nothing. This artifice, employed for the first time by Rumford, has been adopted in nearly every subsequent investigation relating to calorimetry. The experiments of Rumford were followed by those of Crawford, Dalton, and Clement Desormes, and more recently by the investigations of Despretz and Dulong. The researches of the last named physicist were left unfinished at his death, but the results obtained appear to have been much more accurate than those of his predecessors. The most exact and comprehensive researches hitherto made into this subject are, however, those of Favre and Silbermann (Ann. Ch. Phys. [3] xxxiv. 357; xxxvi. 5; xxxvii. 406), and Andrews (Phil. Mag. [3] xxxii. 321 and 426).

Fig. 516.

The calorimeter employed by Favre and Silbermann in their experiments on combustion in oxygen gas, and in other actions whereby large quantities of heat were generated, is represented in section in *fig.* 516, the scale of which is one-fifth of that of the actual apparatus. The calorimeter, properly so called, is the cylindrical vessel CCC, made of copper plated externally with silver and brightly polished, and closed by a cover of the same material. This is surrounded by a second vessel, *b b*, also of silvered copper, but having the polished surface inside, the space between C and *b* being filled with swan's down; outside this again is a third

Digitized by Google

vessel, *ccc*, to the bottom of which *b* is firmly connected by screw-bolts. The annul space which separates this vessel from *b* contains water, the temperature of which indicated by the thermometer *t*, and which serves to neutralise the effect of accident variations of the temperature of the atmosphere. The chamber in which the combu tions take place is made of gilt copper-plate, and is represented by A. When t combustions are to be made in oxygen, the gas, previously purified, enters this chamb by the tube *d*; the products of combustion escape, if gaseous, by the vertical tube *s*, a pass from thence into the serpentine S, where they give up their heat to the water the calorimeter, and then finally leave the apparatus by the upper part of the tube when no gaseous products are formed, the extremity of this tube is closed. If t substance to be burned is a gas, it enters the combustion-chamber by a jet connect with the tube *o*; solid bodies are attached to fine platinum-wires, suspended from t cover B, which closes the combustion-chamber; liquids are burned in small capsul or in lamps with asbestos wicks; charcoal is placed in a sort of sieve, through t openings of which the oxygen has access to it. The progress of the combustion can watched in the mirror *m* through a window in the tube below composed of a triple di of glass, alum, and quartz. The temperature of the water in the calorimeter is ke uniform throughout by means of the agitator *aaa*, which is moved by special mechanis In all cases where it was practicable to do so, Favre and Silbermann deduced t quantity of substance burned from the weight of the products of combustion.

The apparatus employed by Andrews was of much simpler construction. When t substances to be combined were in the gaseous state, and the products of combusti were also gaseous, the two gases were mixed in the proper proportions, as in a eudiom tric experiment, and introduced into a vessel of thin sheet copper, of about 24 cub inches capacity. This vessel was closed by a screw, through which passed a silver wi insulated from it by a cork, and connected by a thin platinum wire within the vess to a second silver wire soldered to the screw itself. By passing a voltaic curre through the platinum wire for an instant, it could be heated to redness and the gaseo mixture exploded. The copper vessel was introduced into a larger vessel, which w filled up with water: this was suspended in a cylinder provided with a movable cove and the whole was enclosed in an outer cylindrical vessel, arranged so as to admit its being made to rotate upon its shorter axis. The apparatus having been mounte was caused to rotate, so as to bring every part to a uniform initial temperature, whi was carefully read off by a very sensitive thermometer. The thermometer was the withdrawn; the gases exploded; the outer vessel of water closed by a cork; and th apparatus caused to rotate for thirty-five seconds. The thermometer was then agai introduced and the rise of temperature ascertained; after which the apparatus wa made to rotate a third time for thirty-five seconds, and the temperature again observe in order to ascertain the cooling effect of the atmosphere upon the apparatus durin the time that the experiment lasted: it was found that this effect seldom exceeded $\frac{1}{4}$ of the total quantity to be measured.

When solid bodies were burned in oxygen, the combustion was effected in a copp vessel, of about 250 cubic inches in capacity, which was filled with oxygen; a know weight of the combustible was placed in a small platinum dish, and when all was ready it was fired by means of a voltaic current sent through a very fine platinum wire. Th vessel in which the combustions took place was immersed in a large cylinder containin a known quantity of water, and surrounded by an outer vessel of tin-plate, to prever radiation. The copper vessel could be moved up and down in the water by means of lever. Particular expedients were sometimes required to insure ignition: thus, i burning zinc-filings and other metals in oxygen, a small fragment of phosphorus (fro 1 to 8 milligrammes) was employed to kindle the metal; the weight of the phosphoru being known, the heat evolved by it could be calculated and deducted from the tota amount produced. Some of these experiments lasted a quarter of an hour and upwards so that the correction for the cooling effect of the air became of considerable importance

When the combustions were made in chlorine, the substance to be burned was en closed in a thin glass bulb, which was broken by agitation after being immersed in th gas; in these experiments it was not necessary to apply heat to cause the combustio to begin. The chlorine itself was usually contained in a glass vessel, filled with it b displacement; in the experiments on potassium, a brass vessel was used, perfectly dr chlorine having no action on brass. An excess of the metal was always used, so as t insure the complete absorption of the chlorine, and the quantity of the latter substanc consumed was, in most cases, ascertained by weighing the quantity of water whic rushed into the vessel after the experiment on opening it under water.

The following table gives the quantities of heat, expressed in heat-units (gramme degrees), evolved in the combustion of various elementary substances in oxygen, referre (1) to 1 grm. of each element burned, (2) to 1 grm. of oxygen consumed, (3) to 1 atom (expressed in grms.) of the several elements.

NOTE.—Andrews' determinations have been recalculated from the original experimental numbers, using the atomic weights and specific gravities of gases adopted in this Dictionary, and therefore the numbers in the above table do not always agree precisely with those contained in the general table of results which he has himself given (Phil. Mag. [3] xxxii. 482).

The following results have been obtained by the complete combustion of partially oxidised substances:

Substance.	Product.	Units of heat evolved		Observer.
		by 1 grm. of substance.	in formation of 1 molecule of the ultimate product.	
Carbonic oxide .	CO^2	{2403 2431	67284 68064	Favre & Silbermann. Andrews.
Stannous oxide .	SnO^2	519	69584	,,
Cuprous oxide .	CuO	256	18304	,,

The substances enumerated in this table contain exactly half as much oxygen as the completely oxidised products, and on comparing the amount of heat evolved in the formation of one molecule of stannic or cupric oxide from the corresponding lower oxide, with the quantity produced when a molecule of the same product is formed by the complete oxidation of the metal in one operation (see previous table), we find that the combination of the second half of the oxygen contained in these bodies evolves sensibly half as much as the combination of the whole quantity. In the formation of carbonic anhydride, however, the second half of the oxygen appears to develope more than two-thirds of the total amount of heat; but this result is probably due, in part at least, to the fact that when carbon is burned into carbonic anhydride, a considerable but unknown quantity of heat is expended in converting the solid carbon into gas, and thus escapes measurement; while, in carbonic oxide, the carbon already exists in the gaseous form, and therefore no portion of the heat evolved in the combustion of this substance, is similarly expended in producing a change of state.

It seems probable also, that a similar explanation may be given of the inequalities in the quantities of heat produced by the combustion of different varieties of pure carbon and of sulphur,—that is to say, that a portion of the heat generated by the combustion of diamond and graphite goes to assimilate their molecular condition to that of wood-charcoal, and that there is an analogous expenditure of heat in the combustion of native sulphur: indeed, with regard to the latter case, it is proved by direct experiments (see p. 102), that the opposite change to that supposed to take place here of recently melted sulphur into the same molecular condition as native sulphur is accompanied by disengagement of heat.

Digitized by Google

In like manner, the heat evolved in combustions may in some cases be in excess of that due to the strictly chemical action which takes place: thus, when the product of combustion is solid, part of the heat must be ascribed to the solidification of the oxygen absorbed. Again, the heat of combustion of hydrogen, as given above, includes the latent heat of vaporisation of the water formed. In Andrews' experiments the temperature of the calorimeter was about 20° C.: at this temperature the latent heat of vaporisation of 9 grms. of water (the quantity formed from 1 grm. or atom of hydrogen) may be taken as = 5500; and deducting this quantity from 33,881, we have 28,381 as the number of units of heat evolved by the chemical combination of 1 grm. hydrogen and 8 grms. oxygen, according to these experiments. Favre and Silbermann do not give the temperature of their calorimeter, but probably the same correction may be applied to their experiments without much error: they then give 34,462—5500 = 28,962 as the true heat of combustion of 1 grm. of hydrogen.

The experiments which have been made on the heat of combustion of definite compounds, other than the three already mentioned, relate almost exclusively to bodies composed of carbon and hydrogen, or of carbon, hydrogen, and oxygen. The results obtained by Favre and Silbermann and Andrews are contained in the following table. The numbers here given represent the total heat produced, and therefore include that due to the condensation of the vapour of water formed in the experiments.

Many of these numbers must be regarded as approximations only (and sometimes as not very close approximations) to the truth. The chief causes of uncertainty with regard to them, besides the difficulties inherent in the experimental determinations themselves, are the different calorimetric properties of the substances examined—differences, that is, in regard to specific and latent heats—and, in some cases, their admittedly doubtful purity. Hence it is impossible to trace any exact correspondence between the composition of the bodies experimented upon, and the amount of heat which they evolve upon combustion. A few general conclusions are, however, indicated with sufficient clearness to make it worth while to dwell upon them briefly.

In the first place it appears that the heat of combustion of a compound is in general less than the heat of combustion of its elements. This rule is verified in the case of all the hydrocarbons given in the table, with the exception of olefiant gas, whose heat of combustion is almost exactly the same as that of its constituents, according to Favre and Silbermann's determinations, and somewhat greater, according to Andrews. When a hydrocarbon is burned into carbonic anhydride and water, the chemical change which takes place consists, not merely in the union of carbon and hydrogen with oxygen, but also in their separation from their previous state of combination with each other. Now, it is an almost self-evident proposition, and one which has moreover received direct experimental confirmation, that whatever may be the calorimetric effect of any given chemical change, the calorimetric effect of its reversal is equal and opposite. Hence, if we suppose the combination of carbon and hydrogen—to form marsh-gas, for example—to be accompanied by evolution of heat, we must suppose that their separation is attended by the disappearance of an equal quantity of heat. The heat produced by the combustion of one molecule of marsh-gas, CH^4, is therefore less than the quantity due to the combustion of one atom of (gaseous) carbon and four atoms of hydrogen, by the quantity of heat absorbed when these atoms separate from combination with each other. Assuming (for want of more certain data) that the heat of combustion of an atom of gaseous carbon is twice that of a molecule of carbonic oxide, we have, for the heat of combustion of $C + H^4$ (in round numbers), $134,600 + (4 \times 34,460) = 272,440$; but the heat of combustion of CH^4 is 209,000, which gives $272,440 - 209,000 = 63,440$ as the number of units of heat produced by the combination of 1 atom of carbon with 4 atoms of hydrogen, or absorbed when these atoms separate. In like manner, we have, for the heat of combustion of $C^2 + H^4$, $(2 \times 134,600) + (4 \times 34,460) = 407,040$ units; and deducting from this the heat of combustion of olefiant gas, we have $407,000 - 332,000 = 75,000$ for the calorimetric effect due to the separation of the atoms of a molecule of olefiant gas from each other. The difference between 63,400 (the heat of formation of CH^4) and 75,000 (the heat of formation of C^2H^4), namely 11,600, may perhaps be taken as representing the calorimetric effect of the combination or separation of the two atoms of carbon contained in olefiant gas. The fact that the heat of combustion of olefiant gas, as found by direct experiment, is very nearly equal to the sum of the heats of its constituents, when the heat of an atom of carbon is taken at 96,960 units, the quantity deduced from the combustion of wood-charcoal, probably indicates that the heat of vaporisation required to change the physical condition of two atoms of carbon from that of wood-charcoal to that which it has in the form of olefiant gas, is nearly the same as the heat required to separate the atoms of a molecule of olefiant gas from each other. That the heat of vaporisation of carbon is very considerable is further indicated by the great difference, already alluded to, between the caloric effect of the first and second atoms of oxygen contained in carbonic anhydride,

chemical or physical, which accompany a given chemical reaction, when we are cussing the quantity of heat produced by it, than because the results arrived at supposed to be numerically accurate. Indeed it is by no means probable that t results are, at best, anything more than roughly approximative; for, to mention other source of uncertainty, the assumption that we have made, that the heat produ by the complete combustion of carbon is twice as great as that evolved by the com tion of the same quantity of carbon in the form of carbonic oxide, is most likely strictly true. For it has been pointed out by Butlerow that the four unit combining capacity (CLASSIFICATION, i. 1010 *et seq.*) possessed by one atom of car are not exactly equivalent to each other in chemical function, and Erlenmeyer suggested, with great probability, that the difference between them is due to differe in the strength of the chemical affinity with which each unit enters into combina (see references in the article FORMULÆ, ii. 704). If this be so, the combinatio an atom of carbon with one atom of oxygen must evolve more heat than the combina of the product so formed (carbonic oxide) with a second atom of oxygen.

The numbers in the above table show that the heat evolved by the combustio equal weights of the hydrocarbons $(CH^2)^n$, homologous with olefiant gas, diminishe their molecular weights increase. But it is not easy to say how far this result may due to accidental causes (the numbers given are deduced from a single experim except in the case of olefiant gas, for which Favre and Silbermann obtained very c cordant results in two experiments), or to the influence of the physical properties the substances. It may be remarked that the isomeric substances, oil of lemons, o turpentine, and terebene, also gave different quantities of heat, although th molecular weights are the same.*

The acids homologous with acetic acid may be regarded, empirically, as for by the combination of the hydrocarbons $(CH^2)^n$ with oxygen; that is, they may considered as products of the partial combustion of the hydrocarbons. Hence, should expect each acid to give out, when burned, less heat than the hydrocarbon c taining the same quantity of carbon and hydrogen, and this is shown by the number the above table, to be really the case, the difference between the heat of combustio an acid and that of a given hydrocarbon being greater in proportion as the acid is m oxidised. Thus, starting from amylene, C^5H^{10}, and comparing with it quantities valeric, butyric, and acetic acids which contain the same quantity of carbon hydrogen, we have the following numbers:

1	molecule amylene,	C^5H^{10}	= 70	produces	804400	units of h
1	„	valeric acid, $C^5H^{10}O^2 = C^5H^{10} + O^2$	= 102,	„	656800	„
1½	„	butyric acid, $1\frac{1}{2}C^4H^8O^2 = C^5H^{10} + O^{2\frac{1}{2}}$	= 110,	„	621200	„
2½	„	acetic acid, $2\frac{1}{2}C^2H^4O^2 = C^5H^{10} + O^5$	= 150,	„	525750	„

Compared in this way, the difference in composition between amylene and val acid, namely O^2, is four times as great as that between valeric acid and butyric a and the corresponding differences in the heats of combustion of these substances exactly almost in the same proportion: but this close agreement is, probably, in gr part accidental: for the heat of combustion of acetic acid is decidedly greater th what might be calculated in the same way.

The table further shows that isomeric substances by no means always give out eq quantities of heat when burned. For instance, acetic acid, $C^2H^4O^2$, produces c siderably less heat than its isomer, formate of methyl; butyric acid, $C^4H^8O^2$, less than isomer, acetate of ethyl; valeric acid, $C^5H^{10}O^2$, less than its isomer, butyrate of meth That differences of this kind would be found to exist, might have been deduced, w considerable probability, from the differences in the chemical constitution of the ac and of the isomeric ethers: for, of the four equivalents of oxygen contained in th compounds, one must be regarded as combined with hydrogen, and the other three wi carbon in the acids; whereas, in the ethers, all four equivalents of oxygen are co bined with carbon. Hence, the differences between the heats of combustion of t acids $C^nH^{2n}O^2$ and those of the isomeric ethers may be ascribed, at least in part, the difference between the heat of combustion of an equivalent of carbon and that an equivalent of hydrogen; but considerations, such as have been already alluded t make it impossible to assign any exact numerical value to this difference.

But, according to the experiments hitherto made, not only do the acids differ fro the isomeric ethers, in the quantity of heat which they produce when burned, but th ethers differ from each other: for instance, acetate of methyl produces more heat tha its isomer formate of ethyl; valerate of methyl, more than its isomer butyrate ethyl; acetate of amyl, more than its isomer valerate of ethyl. It is not easy to sugge any chemical reason for the existence of such differences as these; nor even to discov any empirical relations of a general kind among the experimental results.

* Favre and Silbermann assign to oil of lemons half the molecular weight of oil of turpentine, b without giving any reason for so doing.

Heat produced by reactions in the Wet Way.—Of the various reactions in the wet way, which have been studied calorimetrically, it will be most convenient to consider first those which take place between water and other bodies, since such actions intervene in many other cases also.

Dilution of Acids with Water.—The heat produced by the dilution of strong acids, especially sulphuric acid, has been the subject of many investigations, the most accurate of which are probably those of Favre and Silbermann, Thomsen (Pogg. Ann. lxxviii. 349; xc. 261; Jahresber. 1853, p. 30); and Favre and Quaillard (Compt. rend. l. 1150). We give below a few of the results obtained.

Sulphuric acid, SO^4H^2 = 98.

Thomsen determined the quantity of heat evolved by the mixture of strong sulphuric acid, and of the same previously diluted with different quantities of water, with an excess of water—that is, with so much that any further quantity did not increase the amount of heat evolved. He found that the addition of an excess of water

to 98 grms. (=1 molecule)	SO^4H^2	evolved	17,248	units of heats.
to 116	,, $SO^4H^2.H^2O$	,,	10,848	,,
to 152	,, $SO^4H^2.3H^2O$	,,	6288	,,
to 188	,, $SO^4H^2.5H^2O$	,,	4480	,,

Favre has determined, in conjunction with Silbermann and with Quaillard, the quantity of heat produced by the successive additions of known quantities of water to strong sulphuric acid. Both sets of experiments were made with the mercurial

Digitized by Google

calorimeter already described, and represented in *fig.* 531, p. 28. We give her results published by Favre and Quaillard as being the most recent.

Addition of Water to 98 *grammes* (1 *molecule*) *of Sulphuric Acid.*

Quantities of water added successively. Molecules.	Heat evolved on each successive addition of water.	Total quantity of water added. Molecules.	Total Heat evolved.	Quantities of water added successively. Molecules.	Heat evolved on each successive addition of water.	Total quantity of water added. Molecules.	T

1	. . . 1179·00	4	12776·60	4	32·08	40	1

A little heat was still produced by the addition of the sixtieth molecule of water.

These numbers show that a given quantity of water added to sulphuric acid ev the same quantity of heat, whether it be added all at once, or in successive s portions, and that the heat which a given quantity of water produces is, accordi less in proportion as the amount previously added is greater.

Nitric Acid, $NO^2H = 63$.

The following table gives the results of Thomsen's experiments on the heat evo on adding an excess of water to nitric acid, either undiluted or already containi certain quantity of water. The numbers refer, as usual, to molecular proportio acid and water expressed in grammes:—

NO^2H	mixed with excess of water				evolved	7560	units of heat
(NO^2H + 0·421	H^2O)	mixed with	excess of	water	evolved	5680	,, ,,
(NO^2H +	H^2O)	,,	,,	,,	,,	4088	,, ,,
(NO^2H + 1·5	H^2O)	,,	,,	,,	,,	3760	,, ,,
(NO^2H + 1·59	H^2O)	,,	,,	,,	,,	3464	,, ,,
(NO^2H + 2	H^2O)	,,	,,	,,	,,	2712	,, ,,
(NO^2H + 2·5	H^2O)	,,	,,	,,	,,	2184	,, ,,
(NO^2H + 3·5	H^2O)	,,	,,	,	,,	1392	,, ,,
(NO^2H + 4·5	H^2O)	,,	,,	,	,,	952	,, ,,

It will be observed that the heat which can be obtained by the addition of wate nitric acid diminishes as the quantity of water already present in the acid is gre but that the diminution takes place, at first, much less rapidly than in the cas sulphuric acid.

Acetic Acid, $C^2H^4O^2 = 60$.

The following results are those of Favre and Quaillard: we give them in orde call attention to the absorption of heat (indicated by the *minus* sign in the sec column) produced by the first quantities of water added:

Quantities of water added successively.	Heat evolved on each addition of water.	Total quantity of water added.	Quantities of water added successively.	Heat evolved on each addition of water.	Total quantity of wa added.

These numbers plainly show the simultaneous occurrence of two distinct actions—one of them attended with absorption of heat, the other with its production. The former action prevails at first, but gradually diminishes as more and more water is added, until, on the addition of the fourth half-molecule, its effect becomes less than that of the second, and a small evolution of heat takes place. From this point, until between five and seven-and-a-half molecules of water have been added, the calorific effect of a given quantity of water continually *increases* (contrary to what takes place with sulphuric and nitric acids), showing that the heat-absorbing action still takes place, but to a less and less extent, until more than five molecules of water have been added to each molecule of acetic acid.

When successive quantities of alcohol, up to ten molecules, are added to acetic acid, each addition causes absorption of heat; but the numerical results clearly indicate, in this case also, the simultaneous occurrence of distinct phenomena. Favre obtained the following results:

Molecules of alcohol successively added to 1 molecule of acetic acid	1	1	1	1	2	2	2
Units of heat *absorbed* on the addition of each successive quantity	91·91	0·91	7·35	14·88	31·85	41·47	64·50

Absorption of heat also frequently occurs on the dilution of saline solutions, a phenomenon with regard to which numerous quantitative determinations have been made by Favre. It is probable that in these cases, a change takes place more or less analogous to the liquefaction of a solid by solution: acetic acid, or a salt dissolved in a small quantity of water, may be conceived of as being imperfectly liquefied, so that further liquefaction, accompanied by the disappearance of a certain quantity of heat, takes place on the addition of more water. Viewed in this way, these phenomena appear to be comparable with the gradual melting, which, as we have seen (pp. 74 and 76), takes place in some solids under the direct action of heat.

Reaction of Acids and Bases in presence of water.—It will be easily understood that the thermal effects which may result from the reaction of different substances upon each other in presence of water, are even more complicated than any of those which have yet been considered, and therefore that the calorimetric study of these reactions is subject to still more numerous causes of error than that of the foregoing processes. In addition to the different specific heats of the reagents and products, and to the different quantities of heat absorbed by them in dissolving, or given out by them in combining with water, the conversion of soluble substances into insoluble ones, as a consequence of the chemical action, or the inverse change of insoluble into soluble bodies, are among the secondary causes to which part of the calorimetric effect may be due in these cases. The greater number of these disturbing causes may be got rid of, or at least very much reduced in amount, by effecting the reactions in the presence of comparatively large quantities of water, but then the difficulty of accurately measuring the total quantity of heat produced becomes greater.

The following table gives the number of units of heat evolved, according to Favre

Oxide of	Equivalents.	Units of Heat evolved with Various Acids:			
		Sulphuric.	Nitric.	Hydrochloric.	Acetic.

and Silbermann's experiments, in the transformation of equivalent quantities of various

Digitized by Google

metallic protoxides into neutral salts, the reaction taking place in all cases in presence of a large quantity of water, and the products being all soluble.

The heat evolved by equivalent quantities of potash and soda respectively, in forming neutral salts with the following additional acids, is shown in the next table:

Acids.	Potash.	Soda.	Acids.	Potash.	Soda.
Hydrobromic acid .	15510	15159	Valeric acid . .	. .	13500
Hydriodic acid .	15698	15097	Citric acid . .	13658	13178

Formic acid . .	. .	13308			

Numerous determinations of a similar kind have also been made by Andrews (Trans. Roy. Irish Academy, xix.; Rep. Brit. Associat. 1849, p. 69; see also Miller's *Chemical Physics*, p. 352). The following is the most important of the conclusions at which he arrived:—"An equivalent of the same base, combined with different acids, produces *nearly* the same quantity of heat; but an equivalent of the same acid combined with different bases, produces different amounts of heat." It is, however, scarcely needful to point out, that such a difference as is here implied between the chemical behaviour of acids and bases does not really exist in nature, and that its appearing to be indicated by the experiments in question, could only result from the accident of the bases examined representing a greater range of varying chemical energy than the acids.

The results obtained on bringing together an alkali and an acid in various proportions are of considerable interest. They show clearly that, at least in the case of the most distinctly characterised acids, chemical action takes place only between definite atomic proportions of acid and alkali. The numbers given below represent the number of units of heat evolved by one equivalent of potash or soda (the quantity containing 39 pts. potassium, or 23 pts. sodium) when acted on by varying quantities of acid.

1 equivalent potash
with 1 equivalent sulphuric acid gave 15609 units of heat.
„ 2 „ „ „ „ 15609 „ „
„ 1 „ acetic „ „ 13935 „ „
„ 2 „ „ „ „ 13823 „ „ (Favre and Silbermann).

The results of Thomsen's experiments (Jahresber. 1854, p. 30) with sulphuric acid and potash and soda are as follows:

Equivalents of acid		½	¾	1	1½	2	4
Heat evolved	Soda	5424	10656	15368	15320	15524	15216
	Potash	4968	9880	15368	. .	15248	

It will be seen that the evolution of heat increases sensibly in the same proportion as the quantity of acid used, up to one equivalent, but that beyond this point no further increase in the amount of heat evolved accompanies the augmentation of the quantity of acid. Hence it appears that acid sulphates of potassium and sodium are not formed in presence of a large quantity of water, a conclusion which agrees with Favre and Silbermann's observation, that the evolution of heat which takes place on adding one equivalent of base to a dilute solution of acid sulphate or sulphite of potassium, is the same as if the second equivalent of acid contained in the salt were employed in the free state. By experiments on the heat evolved on adding successive quantities of other acids—such as boric, silicic, phosphoric—to one equivalent of soda or potash, Thomsen found that the heat produced was at first nearly in proportion to the quantity of acid added, but that, as the latter was increased, the evolution of heat increased also, though in a continually slower ratio.

Evolution of Heat in the formation of Aqueous Solutions.—When a gas dissolves in water, the heat due to the chemical action is augmented by that due to the physical phenomenon of the liquefaction of the gas; so also, when a solid body is dissolved in water, the total thermal effect observed is due in part to the chemical action taking place between the water and the solid, and in part to the liquefaction of the substance dissolved. In the former case, the chemical and physical parts of the phenomenon both cause evolution of heat: in the latter case, the physical change occasions disappearance of heat; and if this effect is greater than that due to the chemical action, the ultimate result of the combined process is the production of cold, and it is this which

Digitized by Google

most usually observed. The following tables contain the results of Favre and Silbermann's experiments, calculated for one gramme of gas or solid salt dissolved.

NOTE.—The sign *plus* (+) denotes evolution of heat.

The foregoing table includes numbers relating to the solubility of some salts which are, in reality, either quite insoluble or very slightly soluble in water. These numbers are deduced from a comparison of those which represent the heat of formation of these salts with the numbers expressing the heat evolved by the same bases with other acids. The heat of formation of salts which are insoluble, and therefore separate out in the solid form, is usually considerably greater than the heat of formation of soluble salts of the same bases and acids, and it is this excess which in the above table is given as the heat absorbed on solution by such salts as sulphate of barium, sulphate of strontium, &c.

Cold produced by Chemical Decomposition.—The proposition that the thermal effect of the reversal of a given chemical action is equal and opposite to the thermal effect of that action itself, has already been referred to (p. 106) as one which might with great probability be assumed as true. A direct consequence of this proposition is that *the separation of any two bodies is attended with the absorption of a quantity of heat equal to that which is evolved in their combination.* The truth of this deduction has been experimentally established in various cases by Woods (Phil. Mag. [4] ii. 368; iv. 370); Joule (*ibid.* iii. 481) and Favre and Silbermann, by comparing the heat evolved in the electrolysis of dilute sulphuric acid, or solutions of metallic salts, with that which is developed in a thin metallic wire by a current of the same strength; and by comparison of the heat evolved in processes of combination accompanied by simultaneous decompositions, with that evolved when the same combination occurs between free elements.

Digitized by Google

In the experiments of Woods, a voltaic current was first made to pass through a vessel containing dilute sulphuric acid, and the quantity of gas evolved in a given time was determined, and also the simultaneous rise of temperature, the strength of the current being measured at the same time by the tangent-compass (ii. 460). The electrolytic cell was then removed, and a thin platinum wire introduced between the poles, of such a length as to produce a resistance equal to that of the electrolyte. The quantity of heat evolved in this wire was then determined, and found to exceed that which was previously evolved in the electrolytic cell, by a quantity equal to that which would be evolved by the combination of the oxygen and hydrogen set free by the current in the previous experiment.

Joule made similar experiments on the decomposition of dilute sulphuric acid, sulphate of copper, and sulphate of zinc; and, regarding the difference in the quantity of heat evolved when the current traversed a circuit completely metallic, and when the metallic circuit was broken by the interposition of an electrolyte, as the heat absorbed by the separation of the elements of the electrolyte, he obtained numbers which agree very fairly with those found by other experimenters for the heat evolved in the union of the same elements, as shown in the following table, which gives the quantities of heat evolved or absorbed in the oxidation or reduction of 1 gramme of each metal, according to various experimenters.

	Joule.	Dulong.	Andrews.	Favre and Silbermann.	Grassi.	Woods.
Copper .	594	. .	600	655	. .	611
Zinc . .	1185	1297	1315	1277	. .	1307
Hydrogen .	33553	34587	33808	34462	34666	

The proposition in question has also been confirmed by experiments of another kind. Thus, for instance, by determining the heat evolved when different metals were dissolved in water or dilute acid, Woods found that it was less than that which would be produced by the direct oxidation of the same metals, by a quantity equal to that which would be obtained by burning the hydrogen set free, or which was expended in decomposing the water or acid; and therefore that, when this latter quantity was added to his results, they agreed with the numbers given by experiments of direct oxidation. The quantities of heat evolved by 1 gramme of the several metals, when augmented by that corresponding to the decomposition of the water or acid, were as follows:—

Metal.	Heat by solution of 1 gramme.	Metal.	Heat by solution of 1 gramme.
Sodium . . .	3293	Tin . . .	595
Potassium . .	1745	Lead . . .	256
Zinc . . .	1307	Mercury . .	118
Iron . . .	1204	Silver . . .	96
Copper . . .	611	Bismuth . .	95·5

Indirect methods of determining Heat of Combination.—Assuming the truth of the proposition that in the decomposition of a compound as much heat is absorbed as is liberated in its formation, it is obvious, from the foregoing examples, that the calorimetric effect of a given chemical change can be calculated if the effects of all those which occur simultaneously with it are known. Upon this principle, which is merely that adopted by Woods in the experiments described in the last paragraph, Favre and Silbermann have made a very extensive series of determinations of the quantities of heat evolved in reactions which could not have been easily investigated directly. Their experiments were made with the mercurial calorimeter, and the heat due to a given process was in some cases deduced from two distinct reactions. Thus, the heat of formation of oxide of zinc was deduced (1) from the solution of metallic zinc in dilute sulphuric acid, (2) from the solution of zinc in dilute hydrochloric acid. For the purposes of calculation, the former reaction was considered as consisting in the formation of oxide of zinc, with simultaneous decomposition of water, $Zn + H^2O = ZnO + H^2$, and in the subsequent formation of sulphate of zinc by the action of this oxide on the dilute sulphuric acid, $ZnO + H^2SO^4 = H^2O + ZnSO^4$. The heat absorbed by the calorimeter during the solution of 1 gramme of zinc was 567·9 gramme-degrees: this, according to the supposition, represented the heat of oxidation of the zinc + the heat of formation of sulphate of zinc from anhydrous oxide and dilute sulphuric acid − the heat absorbed by the decomposition of water. Calling the heat of oxidation of one

Digitized by Google

gramme of zinc x, and calculating, from the direct determinations previously recorded, the calorimetric effects of the other processes, we have

$$x = 567{\cdot}9 + 1060{\cdot}4 - 335{\cdot}5 = 1292{\cdot}8.$$

Similarly, when 1 gramme of zinc was dissolved in dilute hydrochloric acid, 503·8 units of heat were absorbed by the calorimeter, and the following equation was obtained to represent the heat of oxidation of that weight of zinc:

$$x = \underset{\substack{\text{Heat absorbed}\\ \text{by calorimeter.}}}{503{\cdot}8} + \underset{\substack{\text{Heat absorbed}\\ \text{by decomposition}\\ \text{of water.}}}{1060{\cdot}4} - \underset{\substack{\text{Heat evolved by}\\ \text{action of dilute}\\ \text{hydrochloric acid on}\\ \text{oxide of zinc.}}}{274{\cdot}3} = 1289{\cdot}9;$$

a result which agrees almost exactly with the foregoing.

This number having been obtained, the heat of oxidation of metallic copper could be deduced in a similar manner from the quantity of heat set free when a known weight of zinc was dissolved in a solution of sulphate of copper. In this way the number 684 was found for the heat of oxidation of 1 gramme of copper.

The following table gives the heats of combination of one equivalent of several metals with one equivalent of various metalloids, deduced from experiments of this kind:—

Metals.	Units of heat evolved by combining with				
	8 grammes oxygen.	35·4 grammes chlorine.	80 grammes bromine.	127 grammes iodine.	16 grammes sulphur.
Hydrogen . .	34462	23783	9322	−3606	2741
Potassium . .	76238*	100960	90188	77268	45638
Sodium . . .	73510*	94847			
Zinc . . .	42451	50296	. .	. .	20940
Iron . . .	37828	49651	. .	. .	17753
Copper . . .	21885	29524	. .	. .	9133
Lead . . .	27675	44730	32802	23208	9556
Silver . . .	6113	34800	25618	18651	5524

Taking the heat developed in the formation of any given compound as a measure of the energy of the affinity of its constituents, a certain definiteness and precision of meaning are given to such terms as strong and weak, active and inert, which are often used in reference to chemical reagents in rather a vague sense; and on comparing the numbers representing the heats of formation of various compounds, they will be found to bear out in a general way the manner in which such terms are commonly applied. The results recorded in the above table, for instance, serve to explain certain facts which have often been quoted as anomalous and opposed to the commonly received idea that the affinities of chlorine are stronger than those of bromine or iodine, and the affinities of bromine stronger than those of iodine. The facts referred to are such as these: the observation of Fehling that in the fractional precipitation of a solution containing both chlorides and bromides with nitrate of silver, the whole of the bromine is contained in the first portions of the precipitate; the similar observation of Field (Chem. Soc. Qu. J. x. 234), and the decomposition of chloride of silver when brought in contact with an aqueous solution of bromide or iodide of potassium, described by the same chemist; and particularly the violent decomposition of chloride of silver, attended with evolution of heat, which takes place, as observed by Deville (Ann. Ch. Pharm. ci. 198), when aqueous hydriodic acid is poured upon it.

The precipitation of bromide or iodide of silver, to the exclusion of the chloride, in cases of fractional precipitation with nitrate of silver, and the conversion of chloride of silver into bromide or iodide by contact with an aqueous solution of iodide of potassium, may be considered as essentially the same phenomenon. When the latter transformation is expressed by an equation, the substances whose formulæ appear in the left-hand member of the equation are those which suffer decomposition; while those which are formed appear on the right-hand side; and on comparing the calorimetric values of the several terms, making due allowance for their state of solution or otherwise, we find that the sum of the calorimetric values on the left-hand side of the equation is less than the sum of the calorimetric values of the substances on the right-hand; thus indicating that, although the conversion of chloride of silver into bromide or iodide by simple substitution would be attended with absorption of heat, the combined effect of all the actions which take place in the experiments under consideration is to cause an evolution of heat.

* These numbers represent the formation of aqueous solutions of potash and soda: all the rest refer to anhydrous compounds.

Digitized by Google

Thus we have

	AgCl + KBr	=	AgBr + KCl
Calorimetric values	34800 85678		25618 97091
Sums:	120478		122709

therefore: heat evolved in the reaction = 122709 − 120478 = 2231 gramme-degre

	AgCl + KI	=	AgI + KCl
Calorimetric values	34800 72479		18651 97091
Sums:	107279		115742

therefore: heat evolved in the reaction = 115742 − 107279 = 8463 gramme-degr

Similarly, for the reaction of aqueous hydriodic acid on chloride of silver, we ha

	AgCl + HI	=	AgI + HCl
Calorimetric values	34800 15004		18651 40192
Sums:	49804		58843

therefore: heat evolved in the reaction = 58843 − 49804 = 9039 gramme-degree

The heat evolved in a considerable number of processes of oxidation has bee directly determined by Favre (J. Pharm. Chim. [3] xxiv. 241, 311, 412; Jahre 1853, pp. 22 *et seq.*), for the most part by effecting the oxidations in presence of w in the mercurial calorimeter, by means of hypochlorous acid, whose heat of forma calculated for one equivalent of chlorine, he found by preliminary experiments t − 7370 units.

For the details of this investigation we must refer to the original papers; the important results obtained are as follows, calculated always for one equivalent of element operated upon.

Substance.	Product.	Heat evolved.	Ratio.
Yellow phosphorus	Aqueous phosphoric acid	209476	4·36
Red phosphorus	Aqueous phosphoric acid	181230

It is obvious that, even supposing the principle upon which these indirect determinations are made to be quite correct, and all the interfering circumstances to have been taken into account, the results arrived at cannot be of the same degree of accuracy as those obtained by more direct methods: for the total uncertainty attaching to all the independent data from which they are deduced will be accumulated upon them. Moreover, although a comparison of the heat of chemical action, as determined directly, with that deduced indirectly, generally shows, in the simple cases in which it is possible to institute such a comparison, a degree of agreement which may be taken as a confirmation of the correctness of the principles whereby the calculated result is arrived at, and as proving that, at least in these cases, no modifying circumstance of any great importance has been overlooked in the calculation, still it cannot be considered as proved by existing experiments that the cold of decomposition is *always* equal to the heat of combination. On the other hand, it seems probable, on general grounds, that the calorimetric effect of a given chemical process is not an absolutely constant quantity, but that it is to some extent dependent on accompanying physical conditions. In particular, it seems likely that it must vary more or less with the temperature at which the chemical action takes place, and therefore—to take a particular example—that the heat *evolved* by the combination of mercury with oxygen, at a comparatively low temperature, is not equal to the heat *absorbed* by the decomposition of oxide of mercury at a higher temperature. The equality of these two quantities of heat would involve also the equality of the specific heat of oxide of mercury with the sum of the specific heats of its elements; otherwise, the quantity of heat needed to raise the temperature of a given quantity of mercury and oxygen from the ordinary temperature to a temperature above that at which oxide of mercury is decomposed, would be different, if the two substances remained uncombined during the process, from what it would be if they first entered into combination and afterwards separated again; and since the final condition of the mercury and oxygen would be the same in each case, the difference between the quantities of heat would have disappeared without producing any apparent effect. In the particular case that has been taken as an example, it is possible that the specific heats of the elementary bodies are together equal to the specific heat of the compound, or that the difference may be compensated by the difference in the latent heats of vaporisation of oxygen at the temperature of combination and at that of decomposition. But, although this may be the case, experimental proof that it is so is still wanting; and even if it were afforded here, or for any other particular substance, there would still not be sufficient warrant for assuming as a generally established fact that the cold of decomposition is equal to the heat of combination, independently of the conditions under which these processes respectively occur. In connection with these considerations, it is perhaps worth while to draw attention to the fact that the heat of combustion of hydrogen, deduced by Joule from the electrolysis of water at the ordinary temperature, is decidedly less than that found by other experimenters who determined directly the heat of combustion at a high temperature (see p. 114). These experiments are perhaps not sufficiently comparable in other respects to justify us in attaching much importance to this result; but, taking it as it stands, it is in harmony with the fact that the specific heat of water-vapour is less than the sum of the specific heats of its constituents.

The laws by which Thomsen considers that the development of heat in chemical action is governed, appear to involve views similar to those above explained. The fundamental propositions assumed by him are as follows:—The intensity of the chemical energy of the same body at a constant temperature is unchangeable; the whole quantity of heat developed in a given chemical action is a measure of the chemical energy therein exerted, and is proportional to the difference between the total chemical energy of the reagents and the total chemical energy of the products.

Heat produced by Chemical Decomposition.—There are a few phenomena which are, at least apparently, exceptions to the general rule that heat is evolved in combination and absorbed in decomposition. It was found, for instance, by Favre and Silbermann, that charcoal evolves more heat by burning in nitrous oxide than by burning in pure oxygen. The excess of heat in this case could only be due to heat evolved in the decomposition of the nitrous oxide, and direct experiments proved that this decomposition was attended with evolution of heat. They found further that heat is produced in the decomposition of peroxide of hydrogen by platinum, and from the experiments of Favre, already recorded, it appears that heat is absorbed in the oxidation of chlorine to hypochlorous or to chloric acid. Perhaps these and similar phenomena may be brought into harmony with the general rule, by taking into consideration the evolution of heat due to the combination of two similar atoms to form a molecule, and the corresponding absorption of heat due to the separation of the atoms constituting a molecule of an elementary body.

The influence of high temperature in promoting chemical action—as, for instance,

Digitized by Google

between oxygen and hydrogen, which combine when heated, but are without action each other in the cold—is not an exception of the kind here referred to. It is rather thermometric than a calorimetric phenomenon; high temperature being a favourable condition for chemical action in these cases, but in no way its cause. At very low temperatures chemical action appears in all cases to be much retarded: as one illustration, it may be mentioned that when liquefied ammonia, cooled to about $-66°$, is poured upon concentrated sulphuric acid, the two liquids form separate layers, and for some time no action takes place between them (Loir and Drion). Phosphorus and iodine, which combine energetically and with vivid combustion at common temperatures, may be shaken together in a tube cooled by a freezing mixture, without exerting the slightest action on each other.

5. *Relations of Heat to Electricity.*

Electricity produced by Heat.—*Pyro-electricity developed in Crystals.*—To what has been already said on this subject in the article Electricity (ii. 411) we have only to add the results arrived at by Gaugain (Ann. Ch. Phys. [3] lvii. 5) in reference to the pyro-electricity of tourmalines. He finds that this phenomenon obeys the following laws:—(1.) When any number of tourmalines are united by their poles of the same name, they form a battery which produces, under any given circumstances, a quantity of electricity exactly equal to the sum of the quantities which the several tourmalines would produce separately under the same circumstances.

(2.) When several prisms of equal section are superposed, the quantity of electricity developed by the combination is merely equal to that which would be furnished, under the same conditions, by any one of the prisms taken separately.

(3.) The quantity of electricity produced by a prism of tourmaline is proportional to its sectional area, and is independent of its length.

(4.) The quantity of electricity which a tourmaline developes when its temperature is lowered a given number of degrees, is independent of the length of time in which the cooling is effected.

(5.) When a tourmaline is heated a given number of degrees, the quantity of electricity developed is precisely the same as that which would be produced if it were cooled to an equal extent.

Gaugain finds that the development of electricity, consequent on the alteration of the temperature of a tourmaline, is very much more marked if one pole of the crystal is placed in electric communication with the earth, than when the crystal is completely insulated.

Thermo-Electricity.—When two bars of dissimilar metals are soldered together at each end, a current of electricity generally circulates through the circuit formed by them, as long as the two soldering points are at different temperatures. The electromotive force developed at each joint is a function of the temperature, which, in the cases that have been specially examined, may be represented by the formula $E = a + bt + ct^2$, where t is the temperature, and a, b, and c are constants depending on the nature of the metals used. Consequently, the resultant electromotive force, when the temperatures of the joints are t and t respectively, may be represented by

$$e = E - E_1 = b(t - t_1) + c(t^2 - t_1^2) = (t - t_1)[b + c(t - t_1)],$$

which shows that the current vanishes not only when the joints are at the same temperature, or when $t = t_1$, but also when the sum of their temperatures attains a value that is constant for the same pair of metals,—that is when $t + t_1 = -\frac{b}{c}$. (Avenarius, Pogg. Ann. cxix. 406, 637.)

Heat produced by Electricity.—The laws regulating the development of heat by the sudden discharge of frictional electricity, or electricity of high tension, have already been treated of in the article Electricity (ii. 395), and in the same article (p. 470) it has been shown that the heat produced by a continuous current of electricity is the exact equivalent of the chemical action whereby the current is generated. In the application of this rule, the total chemical action throughout the circuit must be taken into account, electrolytic decomposition being counted positive or negative according as the direction of the current which would be generated by it, were it to take place independently of the battery, is the same as that of the battery or the contrary. As further explained in the article referred to, the heat developed in the unit of time by an electric current is related to the intensity of the current and to the resistance of the circuit in the manner expressed by the formula:

$$H = I^2R.$$

Digitized by Google

From this it follows that, by diminishing the resistance of the circuit, the electro-motive force remaining the same, the total heat, H, can be augmented indefinitely, the intensity, and therefore also the chemical action in the battery, increasing in proportion to the diminution of resistance. But in any single portion of the circuit, whose resistance is r, the development of heat will attain a maximum for a particular value of r. The heat produced in this part will in fact be $h = I^2 r = \frac{E^2}{(R+r)^2} r$, the value of which last expression reaches a maximum when $R = r$, R being the constant resistance of the remainder of the circuit, including the battery. Hence, in order that as large a quantity of heat as possible may be generated in a given time in the conducting wire, the resistance r of the conducting wire must be made equal to the permanent resistance R of the remainder of the circuit. And, since the heating power of the current represents its total energy, it follows that the same proportion between the external and internal resistance of the circuit is the most advantageous that can be adopted for causing the current to produce changes of any other kind outside the battery.

Thermal phenomena of a particular kind occur when an electric current, instead of traversing a homogeneous conductor, passes from one substance to another. Then, in addition to the development of heat corresponding to the resistance of the conductor, according to the laws stated in the last paragraph, a further development or absorption of heat takes place, depending upon the direction of the current. If the current crosses the point of junction of two dissimilar portions of the circuit, in the same direction as the thermo-electric current which would be generated by the application of heat to this point, then the heat developed there is less than corresponds to the resistance of that portion of the circuit, or, in other words, heat is absorbed; if the current passes the point of junction in the opposite direction, the heat generated is more than what corresponds to the resistance.

With a junction formed of the same two metals, the development or absorption of heat thus occasioned is proportional to the intensity of the current by which the junction is traversed. With combinations of different metals, the extent to which this phenomenon occurs varies with the positions of the metals in the thermo-electric series (ii. 412), being greatest for those combinations which give the most intense thermo-electric currents.

6. *Relations of Heat to Mechanical Energy.*

In preceding parts of this article, we have seen that increase of volume and of elastic force are among the most universal of the effects of heat. In this way heat is constantly producing motion, and when this motion is concentrated in a given solid body, and a definite direction is given to it, as in the steam-engine, heat becomes by far the most important artificial source of mechanical power that we possess. Conversely, innumerable familiar facts supply us with illustrations of the production of heat at the expense of mechanical work. Thus, in all machines there is a certain loss of mechanical energy, the work performed by the machine never representing the full equivalent of the work needed to drive it. That portion of the mechanical energy supplied to the machine which is wasted, so far as the performance of useful work is concerned, is expended in overcoming the passive resistances by which the motion of the machine is opposed; such, for instance, as friction between contiguous surfaces not moving with the same velocity, or the rigidity of straps or cords used to transmit movement from one part to another. But, whenever motion is produced in opposition to friction, or a rigid body is forcibly bent, heat is generated; the mechanical energy expended in producing these effects is lost to the purposes of the machine, but the heat evolved is its representative. Percussion is another means by which mechanical energy can be destroyed and heat generated in its stead. These and similar facts have long attracted the attention of philosophers, and great importance has been attached to them in reference to most of the theories that have been suggested from time to time to explain the nature of heat and the effects which it produces. The following is a quotation from Black's *Lectures on Chemistry* (vol. i. pp. 31, 32), and relates to Bacon's investigations into the nature of heat contained in his treatise *De formâ Calidi*:—

"The only conclusion, however, that he" (Lord Verulam) "is able to draw from the whole of his facts, is a very general one, viz. that heat is motion.

"This conclusion is founded chiefly on the consideration of several means by which heat is produced, or made to appear, in bodies; as the percussion of iron, the friction of solid bodies, the collision of flint and steel.

"The first of these examples is a practice to which blacksmiths have sometimes recourse for kindling a fire; they take a rod of soft iron, half an inch or less in thickness, and, laying the end of it upon their anvil, they turn and strike that end very quickly on its different sides, with smart blows of a hammer. It very soon becomes

Digitized by Google

red hot, and can be employed to kindle shavings or wood, or other very combustible matter.

"The heat producible by the strong friction of solid bodies, occurs often in some parts of heavy machinery, when proper care is not taken to diminish that friction as much as possible, by the interposition of lubricating substances; as in the axles of wheels that are heavy themselves, or heavily loaded. Thick forests are said to have taken fire sometimes, by the friction of branches against one another in stormy weather. And savages, in different parts of the world, have recourse to the friction of pieces of wood for kindling their fires. . . . .

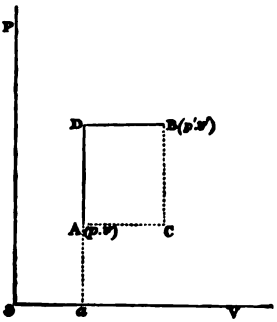
"The third example above adduced in the collision of flint and steel, is universally known.

"In all these examples, heat is produced or made to appear suddenly, in bodies which have not received it in the usual way of communication from others, and the only cause of its production is a mechanical force or impulse, or mechanical violence."

From these and many other similar phenomena, it is abundantly clear that, by the expenditure of heat, mechanical work can be effected, and that heat can be produced by the expenditure of work. Dismissing, therefore, for the present, all considerations as to the ultimate nature of heat, we may say that heat and work are mutually convertible, and we have in this section to consider the conditions which regulate the transformation of one of these forms of energy into the other.

Work produced by Heat.—The measure of the work done by heat, when it causes expansion, is obviously the product of the resistance overcome into the space through which the expansion takes place; that is, if r denote the resistance, and v and v' the initial and final volumes of the body which undergoes expansion, the work done by the heat will be represented by

$$A = r(v' - v).$$



In estimating the resistance by which the expansion of a given body is opposed, it is needful to take into account, not only the external pressure upon its surface, but also, as has been already pointed out (pp. 40 and 73), the molecular forces which tend to maintain unaltered the relative positions of its ultimate particles. The work, A, performed by heat when it causes expansion, must therefore be considered as made up of the *internal work*, a_i, performed in opposition to internal molecular forces, and the *external work*, a_e, expended in overcoming external pressure. In solid and liquid bodies the ratio, $\frac{a_i}{a_e}$, of the internal to the external work is very considerable, but in a perfect gas, the resistance to expansion arising from the mutual attractions of the molecules is insensible, and therefore also the expenditure of work in overcoming this resistance is insensible: hence, in this case $\frac{a_i}{a_e} = 0$, or $a_e = A$. But since it is the external work only which is available for the production of external effects, the consideration of the transformation of heat into mechanical energy is much simpler in the case of gases than in that of liquid or solid bodies; it is further much the most important practically, for although the heat employed in the performance of internal work upon solids or liquids is not necessarily lost ultimately, it is, for the time at least, totally unavailable. We may perhaps compare the transformation of heat into work with the commercial transformation of labour into wealth: then, a perfect gas will represent a medium of transformation comparable with an industrial process which requires no previous expenditure on the part of the workman to enable him to exchange his labour for wages; while a solid or liquid will represent a medium of transformation comparable with a process which can only be carried out by the previous investment of a considerable capital. The capital thus "sunk" may be realised again at some future time, but it represents a certain quantity of labour, which, for the time being, cannot be transformed into wealth.

In order that work may be continuously performed by heat, it is not enough that a portion of air or other gas should be expanded once for all in a cylinder closed by a piston, or in any other similar apparatus. It is true that motion would be thus produced, and that this might be the full equivalent of the heat expended, but the process would soon come to an end. Practically, the extent to which a gas can be expanded so as to produce motion, is very limited, both by the size of the apparatus that can be used and by the temperatures that are attainable. In order that the process may be continuous, the action of the machine, by means of which the transformation is effected, must be periodic: after a certain cycle of changes, all its parts must return to the same relative positions and condition as they had at first, and the air or gas must return to its original pressure and temperature. Such a cycle might evidently be repeated indefinitely, and if any transformation of heat into work were effected by it, the same amount of transformation would take place each time the cycle was completed.

Digitized by Google

pages 50 and 51, we saw that in the passage of a gas through a succession of conditions, with respect to temperature, pressure, and volume, which can be represented graphically by a rectangle, and are such that the final state of the gas is the same as its state at the beginning of the process, a certain quantity of heat is expended, which is proportional in amount to the area of the rectangle representing the succession of changes; but it was not there explained what becomes of the heat thus expended.

Fig. 547.

Returning to the consideration of this case, and using the same notation as before, it is plain that, during the passage of the gas from the state A to the state B, through the intermediate stages represented by the lines AD, DB, a quantity of work is performed, which is represented, in kilogramme-metres, by

$$A = p'(v' - v);$$

and that while the gas returns from the condition B to the condition A, along BCA, there is expended a quantity of work represented by

$$A' = p(v' - v);$$

and, therefore, during the whole cycle ADBCA, a quantity of work is ultimately gained equal to

$$A - A' = (p' - p)(v' - v).$$

But, by the last equation on page 51, the amount of heat expended at the same time is

$$Q - Q' = \frac{D}{Ha}(c' - c)(p' - p)(v' - v);$$

therefore, between the heat expended and the work produced, there exists a relation expressed by the equation

$$Q - Q' = \frac{D(c' - c)}{Ha}(A - A') \quad . \quad . \quad . \quad . \quad (n).$$

If we assume that the difference between the specific heat under constant pressure and the specific heat at constant volume is constant for each gas, and is inversely proportional to its density (a relation which is implied in equation (*a*), p. 42), the coefficient of $(A - A')$ in this expression is constant; we may therefore represent it by $\frac{1}{E}$, and write equation (*n*) thus:

$$Q - Q' = \frac{1}{E}(A - A') \quad \text{or} \quad E(Q - Q') = A - A'.$$

That is to say, the heat expended is proportional to the work performed, and *vice versâ*; so that for each kilogramme-degree of heat expended, a quantity of work is performed equal to E kilogramme-metres.

The value of E can be deduced from equation (*n*) by introducing the numerical values of the constants, namely:

$$H = 10{,}333 \text{ kilogr.}, \quad a = 0{\cdot}003665, \quad D = 1{\cdot}293 \text{ kilogr.}$$
$$c' = 0{\cdot}2374, \quad \text{and } c = 0{\cdot}168 \text{ (p. 42).}$$

These values give us:

$$E = 423;$$

that is to say, when heat is transformed into work, every kilogramme-degree of heat (1000 of the heat-units hitherto employed in this article) consumed generates 423 kilogramme-metres of work; or, more generally, the heat needed to raise the temperature of any given weight of water from 0° to 1° C., is equivalent to the amount of mechanical energy required to raise 423 times the same weight of water through one metre from the surface of the earth.

The ratio E is therefore called the **mechanical equivalent** of the unit of heat, and its reciprocal is, as we shall see, the **thermal equivalent** of the unit of work.

That the relation between the heat expended and the work generated is necessarily constant, whatever the process may be by which one is transformed into the other, results from the following considerations. If by one process a unit of heat could be made to perform E units of work, and by another process $E + \epsilon$ units of work could be generated by the same quantity of heat, a portion of the mechanical energy produced in this second process might be expended in reversing the first, so as to regenerate the

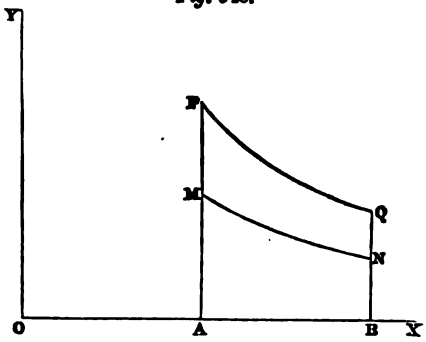
Digitized by Google

original quantity of heat: thus by combining the two processes, the first being worked backwards, each unit of heat expended would reproduce itself and e units of work *in addition*; there would thus be generation of mechanical energy without any corresponding annihilation of any other form of energy. (The principle here implied, that a given quantity of work is capable of giving rise to as much heat as is needed for its own production, results from the above equation (n), but it will be further considered in what follows.)

Nevertheless, in consequence of the unavoidable defects of all experimental processes, the values of E deducible by different methods are not exactly equal, but the agreement between them is quite sufficient to establish the fundamental principle of the real constancy of the relation between heat and work. A table giving the results of the most important determinations of this ratio will be found further on under the head Heat produced by Work.

Under all circumstances, the quantity of heat which must be employed in order to effect the transformation of a given amount of it into work considerably exceeds the quantity transformed. In the example above considered, the total quantity of heat imparted to the gas was Q; but of the work, A, generated by this amount of heat during the passage of the gas from the state A to the state B, a certain portion, A', was employed, during the return of the gas to its initial state, in regenerating the quantity of heat Q'. The useful work performed was, therefore, $A - A'$, and the quantity of heat transformed was $Q - Q'$, and the ratio of this to the total heat employed, namely, $\frac{Q - Q'}{Q}$, represents the efficiency of the process of transformation, or the value of the engine in which it takes place as a source of mechanical energy. The maximum value which this fraction is capable of attaining, depends on the range of temperature passed through by the fluid which is the medium of transformation. This can be most easily demonstrated in a case where the changes of the volume of the gas take place at constant temperatures; that is, where it is kept at one temperature during the whole process of expansion and at another during the whole process of contraction.

These conditions are approximately realised practically in the air-engine invented by the Rev. Robert Stirling, in 1816. This engine consists essentially of two cylinders; a larger one to which the heat is applied, which we may call, for distinction, the heating cylinder, and a smaller one, which may be called the working cylinder, wherein the tranformation of heat into work takes place. The bottom of the working cylinder is connected by a pipe without a valve with the top of the heating cylinder. Within the heating cylinder is a plunger, composed of non-conducting materials, which occupies nearly half its length, and between it and the sides of the cylinder are passages by which the air can pass from one end to the other when the plunger is raised or lowered. In the working cylinder is a piston which fits it air-tight; this piston and the plunger of the other cylinder are both attached by connecting rods to cranks fixed to the same axle, but making an angle of ninety degrees with each other. The heating cylinder is closed at the top, and the rod from which the plunger hangs passes through an air-tight stuffing box; the working cylinder is open at the top. Heat is applied to the bottom of the heating cylinder, and the upper part is kept cool.



The action of the engine is as follows: Suppose the plunger to be at the top of the heating cylinder, and consequently, the piston in the working cylinder in the middle of its stroke; then, if heat is applied to the bottom of the heating cylinder, the air contained there below the plunger will be expanded, and will press the piston upwards; but the motion of the piston being communicated through the axle to the plunger, the latter will descend, and displacing the heated air from the bottom of the heating cylinder, drive it into the cool space at the top. The elastic force of the air being thus diminished, the piston will be forced down by the pressure of the air upon its upper surface; the plunger now returning to the top of the heating cylinder, the air will be driven to the bottom, where it will be again heated, and the piston will be again forced up by its expansion. Thus by the alternate heating and cooling of the same quantity of air, the motion of the engine is kept up.

In consequence of the manner in which the piston and plunger are respectively connected with the axle, each attains its maximum velocity while the other is at rest, so that the action of the engine during one revolution may be considered as essentially made up of four periods: in the first, the temperature of the air is raised, its volume remaining the same, and consequently its pressure increasing; in the second, the air expands, performing work, but so much heat is imparted to it during the expansion, that its temperature remains constant; in the third period, the temperature of the air is reduced to what it was at the beginning of the first period, its volume being unaltered, and therefore its elastic force being diminished; and in the fourth, it is compressed to its original volume, the heat generated by the compression being withdrawn, so that the air remains at the same temperature throughout the whole process. These four

Digitized by Google

successive operations, constituting together one cycle in the action of the engine, may be represented by a diagram such as *fig.* 548, where the abscissa O A represents the volume v_0, of a unit of weight of air at the initial temperature t_0, and the ordinate A M represents the corresponding pressure p_0. The air is first heated, without change of volume, from the temperature t_0 to the temperature t_1; during this operation, its elastic force increases to p_1, represented in the diagram by the ordinate A P; and to effect this change a quantity of heat equal to $c(t_1 - t_0)$ must be imparted to it, c being the specific heat of air at a constant volume; but as no expansion takes place, no work is performed. Next, the air expands from the volume v_0 to the volume v_1, represented by the abscissa O B. Since the temperature of the air is kept constant while it expands, the pressure varies inversely as the volume, a relation represented by the hyperbolic arc P Q, so that the final pressure of the expanded air is represented by the ordinate B Q. During this operation, external work is performed, which is obviously proportional to the area A P Q B, contained between the arc P Q, the axis of abscissæ, and the two ordinates A P and B Q. But in order to prevent the cooling of the gas during its expansion, a quantity of heat, q, must be given to it, of which the mechanical equivalent is exactly the external work which this area represents. In the third operation, the air is cooled to its initial temperature t_0, its volume remaining unaltered, and therefore no work being generated or expended. The pressure is thus reduced from B Q to B N, and a quantity of heat requires to be withdrawn equal to $c(t_1 - t_0)$. Lastly, the air is compressed, while kept at the constant temperature, t_0, to its original volume v_0. To effect this, work must be expended and heat must be removed from the air. The relation between volume and pressure being represented by the hyperbolic arc N M, the work needed for the compression of the air is represented by the area A M N B, and is precisely the mechanical equivalent of the quantity of heat, q', which must be withdrawn from the air in order to maintain its temperature constant during the process.

Fig. 548.

Accordingly, during the first two operations, the air receives a quantity of heat equal to $c(t_1 - t_0) + q$, and develops a quantity of external work geometrically represented by the surface APQB. In the two following operations the air loses a quantity of heat equal to $c(t_1 - t_0) + q'$, and there is expended a quantity of work geometrically represented by the surface AMNB. The ultimate useful expenditure of heat is, therefore, $q - q'$, and the available quantity of work generated is represented by the area MPQN, or the difference between APQB and AMNB. The total expenditure of heat, during the complete cycle of operations, is q; the quantity q' given out by the air during its compression at the temperature t_0 cannot in any way be made available for the maintenance of the action of the machine, and may therefore be considered as entirely lost. The quantity of heat $c(t_1 - t_0)$, which the air gives out when cooled from the temperature t_1 to the temperature t_0, may, on the contrary, be employed to heat another quantity from t_0 to t_1, and, therefore, does not make part of the ultimate expenditure. The reason why this portion of heat can be recovered, while the quantity q' cannot, is, that it is heat of a higher temperature, whereas q', being heat of the temperature t_0, is useless for heating any body to a temperature higher than t_0. The ratio of the useful expenditure of heat to the total expenditure is, therefore, $\frac{q - q'}{q}$.

The values of the quantities q and q' can be found as follows:—representing the mechanical equivalent of heat by E, we have, as a consequence of the above discussion,

$$Eq = \text{surf. APQB}, \quad \text{and } Eq' = \text{surf. AMNB},$$

and consequently

$$\frac{q - q'}{q} = \frac{\text{surf. APQB} - \text{surf. AMNB}}{\text{surface APQB}}.$$

But PQ and MN, being each an arc of a rectangular hyperbola of which the lines of no volume and no pressure, OY and OX, are the asymptotes, it follows that the surface

Digitized by Google

APQB is to the surface AMNB as AP to AM. Therefore, $\frac{q - q'}{q} = \frac{AP - AM}{AP}$ $= \frac{p_1 - p_0}{p_1}$. But p_1 and p_0 are the pressures exerted by the same mass of gas under the same volume, v_0, at the two temperatures t_1 and t_0; consequently, $\frac{p_1}{p_0} = \frac{a + t_1}{a + t_0}$ (by equation *b*, p. 45), and—

$$\frac{q - q'}{q} = \frac{p_1 - p_0}{p_1} = \frac{(a + t_1) - (a + t_0)}{a + t_1} = \frac{\tau_1 - \tau_0}{\tau_1},$$

τ_1 and τ_0 representing the absolute temperatures (see p. 52) corresponding to the centigrade temperatures t_1 and t_0.

A similar investigation of any other engine in which work is generated by the expenditure of heat in causing the alternate expansion and contraction of a gas, would lead to the same expression for its maximum efficiency; hence, in every air-engine, whatever its mode of action, provided no heat is spent uselessly in causing changes of temperature, the ratio of the useful expenditure of heat to the total expenditure is equal to the difference of the absolute temperatures between which the engine works, divided by the highest of these temperatures.

The agreement of this theoretical deduction with the results of practical experience, is one of the most conclusive arguments that can be brought forward in favour of the view which regards heat as a mode of energy convertible into mechanical energy, and in opposition to the older view, according to which heat is regarded as an indestructible entity, and the production of mechanical energy by it, as depending upon its transference from a hotter to a colder body. According to this latter theory, the efficiency of an air-engine ought to be much greater than that of a steam-engine,—a conclusion which has not, however, hitherto been confirmed in practice. Taking a special example, the quantity of heat transformed into work, compared with the total heat supplied to a steam-engine, might be calculated upon this theory, as follows:—Let the engine be supposed to be worked at a pressure of 5 atmospheres, and consequently at the temperature 152°. Each kilogramme of saturated steam supplied to the cylinder at this temperature requires for its formation, according to Regnault's experiments (p. 97), 653 kilogramme-degrees of heat, *minus* the heat contained in the water with which the boiler is fed. If we suppose the engine to be worked expansively, down to the pressure of the atmosphere, and that the steam remains saturated during the expansion, it will escape into the atmosphere with the temperature 100°, and when cooled again to the temperature t, of the water supplied to the boiler, each kilogramme will give out $637 - t$ kilogramme-degrees of heat: under these conditions, therefore, the steam only loses, during its expansion in the engine, $(653 - t) - (637 - t) = 16$ degrees of heat out of the whole quantity contained in it. If t, the initial temperature of the water, be 10°, for example, 643 kilogramme-degrees of heat will have been required to generate each kilogramme of steam, and the fraction $\frac{16}{643}$, or not quite $\frac{1}{40}$, will represent the proportion of the total heat which has been converted into mechanical energy. The value of this fraction may be increased somewhat by adding a condenser to the engine, so as to obtain a greater range of expansion. If, for example, the temperature of the condenser is 40°, and the steam expands in the cylinder until its tension is the same as that in the condenser, or 55 millimetres, conditions which are never quite attained in practice, the quantity of heat given up to the condenser by each kilogramme of steam will be $619 - 40 = 579$ kilogramme-degrees; and if the boiler is fed with the condensed water at the temperature 40°, the formation of this quantity of steam will have required $653 - 40 = 613$ kilogramme-degrees. In this case, therefore, $613 - 579 = 34$ parts of heat will be converted into work out of every 613 parts imparted to the boiler: accordingly $\frac{34}{613}$, or very nearly $\frac{1}{18}$, will be the fraction representing the efficiency of the engine.

This calculation (borrowed from Regnault, Mém. Acad. Sciences, xxvi. introd. pp. v. vi.), it will be observed, supposes that all the heat which is not regained in the condenser, or contained in the steam which escapes into the atmosphere, has been converted into work: nevertheless, the efficiency of the engine comes out much below what is actually attained in practice. By careful experiments on large engines, of upwards of 100 horse-power, in which the loss of heat by radiation and conduction, or by other accidental causes, was estimated and allowed for, as accurately as possible, Hirn found that the difference between the quantity of heat supplied to the boiler, and that absorbed by the condenser, amounted to between $\frac{1}{10}$ and $\frac{1}{5}$, on an average to about $\frac{1}{6}$, of the former quantity. Practically, therefore, the steam engine is between twice and three times as efficient a machine as would appear from the above calculation.

The key to this contradiction between theory and practice, lies in a false assumption that has been made in the calculation. It was assumed that, when saturated steam

Digitized by Google

expands in the cylinder of a steam-engine, it remains in the state of saturated steam, and the heat contained in it was estimated, in accordance with this supposition, from Regnault's determinations of the total heat of saturated steam at various temperatures. In fact, however, saturated steam, if it performs external work while expanding, suffers partial condensation at the same time, and the latent heat of vaporisation of the steam which condenses becomes available for the production of work in the cylinder. It is not therefore saturated steam which escapes from the cylinder of an engine working under the conditions we have supposed, but a mixture of steam and water, containing a quantity of heat, less than the total heat of vaporisation of an equal weight of saturated steam at the same temperature by the latent heat of vaporisation of the proportion of water present. The necessity of this condensation was deduced by Rankine in 1849, and soon afterwards by Clausius, as a necessary consequence of the existence of the mechanical equivalent of heat, and shown to be the principal cause of the accumulation of water in unjacketed steam-cylinders, which had long been known as a practical inconvenience in the working of steam expansively. The beneficial effect of employing superheated steam, and of enclosing the cylinder in a steam-jacket, is that the steam can then expand, performing external work, without undergoing liquefaction. The condensation of aqueous vapour, when it does work on expanding, is distinctly seen in the formation of a mist under an air-pump receiver, containing moist air, when the piston of the pump is raised.

The fact that a considerable part of the heat supplied to a steam-boiler is consumed in converting the water into steam, is not therefore a reason why an air-engine, in which no portion of heat is similarly expended in causing a change of state, should be more efficient than a steam-engine; and the investigation of the conditions under which work is generated in the steam-engine leads to the general result, that the efficiency of any heat-engine is independent of the nature of the fluid which is the medium of transformation of heat into work, and which may be air, steam, or any other vapour or gas; but that, supposing the reception of heat to take place wholly at one temperature, and the rejection of heat wholly at another, the heat transformed into mechanical energy, is to the whole heat received by the fluid, as the range of temperature is to the absolute temperature at which heat is received, and that, between given limits of temperature, the maximum efficiency is attained when the reception and rejection of heat take place, in the manner just stated, at the highest and lowest temperatures respectively.

The most conclusive confirmation of this result is that when it is applied to the calculation of the mechanical equivalent of heat from Hirn's experiments on large steam-engines already referred to, the mean number found is 413, which differs by only 2½ per cent. from that deduced at the beginning of this section from the thermodynamic properties of air.

Heat produced by Work.—In the introduction to this article (p. 16), it is pointed out as a general fact that heat may be generated by reversing any of its effects. A process by which heat is made to generate work may, therefore, by reversal, become a process for the conversion of work into heat. But, as mentioned at the place quoted, mechanical energy may be transformed into heat by non-reversible processes, such as its expenditure in friction or percussion. There are also indirect methods of transforming work into heat which cannot be reversed, step by step; for instance, mechanical energy, used to give motion to a magneto-electric machine, can be caused to generate electricity, and this electricity, if not expended in effecting chemical changes or in reproducing mechanical energy, takes the form of heat in traversing the conducting wire, although by applying heat to the homogeneous conductor, electricity could not be regenerated. This, therefore, is an indirect, non-reversible, process of transformation. But it is found that whether the process by which mechanical energy, or work, is converted into heat is direct or indirect, reversible or non-reversible, the quantity of heat generated by a given quantity of mechanical energy expended is, within the limits of experimental error, always the same, and, within similar limits, the same as the quantity of heat required to regenerate the original quantity of mechanical energy.

The simplest mode of transforming work into heat, is perhaps the compression of a gas, by which means, as in the familiar experiment of the fire-syringe, a temperature sufficiently high to inflame easily combustible substances can be produced without difficulty. The generation of heat in this manner can be made a continuous process, by alternately compressing the gas at a high temperature and allowing it to expand at a low temperature. The reversal of the four operations represented by the diagram, *fig.* 547, p. 121, would constitute such a process, and by the application of reasoning such as that previously employed in the consideration of this case, it is evident that the work which it would be necessary to expend, in order to effect this reversal, would be represented by $A - A'$, and that the heat generated thereby would be

$$Q - Q' = \frac{1}{E}(A - A'),$$

E, being as before, the mechanical equivalent of heat.

Digitized by Google

The expenditure of mechanical energy in compressing liquid and solid bodies is also attended with the production of heat. According to Thomson, the thermal effect of compression may be expressed by the formula:

$$\theta = \frac{\tau a p}{E c},$$

where θ is the effect in question, τ the absolute temperature, a the coefficient of expansion by heat, p the pressure, E the mechanical equivalent of heat, and c the specific heat of the substance. This formula has been verified by Joule (Proc. Roy. Soc. ix. 496) by experiments on water and upon oil, the temperatures varying in the first case between 1·2° C. and 40·4°, and the pressures between 15·64 and 25·34 atmospheres; in the experiments on oil the temperature was always about 17° and the pressures were varied from 7·92 atmospheres to 25·34. In the experiments on water at 1·2°, pressure caused a lowering of temperature instead of a rise, as in the other experiments,—a result which agrees with the fact that water contracts by heat at this temperature. Similarly, when weights are laid upon metallic pillars, heat is evolved, and is absorbed when they are removed, the quantity evolved or absorbed increasing with the weights employed (Joule, *ibid.* viii. 564). Conversely, the stretching of metallic wires causes heat to disappear. Joule found (*ibid.* viii. 355) that an iron wire, $\frac{1}{4}$ inch in diameter was cooled $\frac{1}{4}$ degree C. when stretched by a weight of 775 lb. Similar results were obtained with cast iron, hard steel, copper, and lead. The thermal effects were in all cases found to be almost identical with those deduced from Professor Thomson's theoretical investigation, the particular formula applicable to the case in question being $Q = \frac{\tau a p}{E}$, where Q is the heat absorbed in a wire one foot long, and the other symbols have the same significations as above. Vulcanised india-rubber, which, when stretched, contracts by heat (p. 73), became hotter when the stretching weight was applied, and colder when it was removed. Similar results have been obtained by Edlund, (Ann. Ch. Phys. [3] lxiv. 245), whose experiments lead to the following general conclusions:—

1. When a metal is stretched, without exceeding its limits of elasticity, a cooling effect is produced proportional to the mechanical force employed to stretch it.

2. If the metal afterwards return to the original volume, performing in so doing a quantity of external work equal to that expended in stretching it, it is heated to the same extent as that by which it was previously cooled, and consequently proportional to the mechanical force by which the metal was kept in the stretched state before contracting.

3. If on the other hand, the metal resumes its original bulk without performing external work, it is more strongly heated than in the previous case, and the difference between the two heating effects is proportional to the external work performed, in the one case, by the metal during its contraction.

4. From these three principles, it follows that when a metal passes from the volume V_0 to the volume V_1, without exceeding the limits of perfect elasticity, the accompanying calorific effect does not depend solely upon the initial and final volumes, but also upon the manner in which the entire change takes place.

Experimental Determination of the Mechanical Equivalent of Heat.—It is obvious that any of the processes whereby work is transformed into heat, or heat into work, may serve for the determination of the numerical ratio existing between the unit of work and the unit of heat, provided the process is such as to admit of the accurate measurement of the work or heat expended and of the heat or work produced. The earliest attempt to ascertain the value of this ratio appears to have been made by Count Rumford. His experiments described in his essay, entitled *An Experimental Inquiry concerning the Source of the Heat which is excited by Friction* (read before the Royal Society, January 25, 1798, and published in the Phil. Trans., also in "*Essays, Political, Economical, and Philosophical*, by Benjamin Count of Rumford," 3 vols. 8vo, Lond. 1798–1802, vol. ii. p. 469), were made by pressing a blunt steel borer against the bottom of a cavity made in a brass cylinder which was caused to revolve, while the borer was kept stationary. Considering the state of opinion at the time as to the probable nature of heat, these experiments, and especially the conclusions drawn from them by their author, are very remarkable, but it is only of late years that they have attracted the attention which they deserve. In the most complete experiment, the brass cylinder was placed inside a wooden box containing 18·77 lb. avoirdupois of water; the temperature of the water at the beginning of the experiment was 60° F., and was found to rise continuously when the cylinder was set in motion, until at the end of 2½ hours the water boiled. Rumford states the results of this experiment in a tabular form, taking account of the weights and specific heats of the brass cylinder and steel borer, and gives the total quantity of heat produced, exclusive of the amount accumulated in the wooden box, and of that which was lost by radiation, as sufficient

Digitized by Google

to raise the temperature of 26·58 lb. of water 180 degrees Fahrenheit, or from the freezing to the boiling point; he then quotes experiments by Crawford and by himself, from which he concludes "that the quantity of heat produced equably, or in a a continual stream (if I may use that expression), by the friction of the blunt steel borer against the bottom of the hollow metallic cylinder, in the experiment under consideration, was *greater* than that produced equably in the combustion of *nine wax candles*, each $\frac{3}{4}$ of an inch in diameter, all burning together, or at the same time, with clear bright flames."

The two paragraphs which follow this are especially remarkable, as they show that Rumford distinctly saw the source of this heat in the mechanical energy which was expended during its production:—

"As the machinery used in this experiment could easily be carried round by the force of one horse (though, to render the work lighter, two horses were actually employed in doing it), these computations show further how large a quantity of heat might be produced, by proper mechanical contrivance, merely by the strength of a horse, without fire, light, combustion, or chemical decomposition; and, in case of necessity, the heat thus produced might be used in cooking victuals.

"But no circumstances can be imagined, in which this method of procuring heat would not be disadvantageous; for more heat might be obtained by using the fodder, necessary for the support of a horse, as fuel."

After bringing forward arguments and direct experiments to prove that the evolution of heat cannot have been due to an alteration in the capacity for heat of the particles of metal detached from the larger solid masses by the friction, and that it cannot have been furnished by the air, nor by the water, nor by the pieces of metal by which the cylinder and borer were supported, he says:—"It appears to me to be extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated, in the manner the heat was excited and communicated in these experiments, except it be MOTION."

According to Joule's reduction of these results, they indicate that the heat required to raise the temperature of a pound of water one degree Fahr., is equivalent to the mechanical energy represented by 1034 foot-pounds. This number differs considerably from that deduced from the more accurate experiments to be described below; but the difference is of the kind that might have been anticipated, and, considering the manner in which Rumford's experiments were made, it is not excessive. It will be seen that these were not of a kind to furnish accurate data for determining the quantitative relation between heat and work, and it even seems likely that the idea of instituting a comparison between these two quantities first occurred to Rumford after the experiments were finished, his idea, during their performance, having been rather qualitative than quantitative, and his primary object, as indicated in the title of his paper, to ascertain the nature of the source of the heat developed by friction. But, although the numerical results of this investigation were not sufficiently definite to possess any great value, the investigation, as a whole, is of great importance as indicating a distinct stage in the development of ideas concerning the nature of heat and its relations to other forms of energy; and it is for this reason that we have devoted to it so comparatively large a share of space.

These ideas seem to have advanced but little beyond this point until about the year 1842. In that year J. R. Mayer introduced into science the expression "mechanical equivalent of heat" (Ann. Ch. Pharm. xlii. 233; Phil. Mag. [4] xxiv. 371), and thereby—probably as much as by the calculation of the numerical value of this equivalent, founded upon the then inaccurately known ratio of the two specific heats of air—contributed to promote the general adoption of the view that heat and work are mutually convertible. In the same year, Colding, of Copenhagen, communicated to the Royal Society of Denmark experiments on the production of heat by friction, from which he concluded that the evolution of heat was proportional to the mechanical energy expended, and independent of the nature of the substances between which the friction took place. But it was Joule who was the first to publish experiments which were at the same time sufficiently varied and sufficiently accurate to attract the general attention of scientific men, and to be accepted by them as definite proof that the transformation of mechanical energy into heat, or of heat into mechanical energy, takes place in every case according to a constant numerical ratio.

Joule's first experiments, bearing directly upon the subject, were published in 1843 (Phil. Mag. [3] xxiii. 441). In this investigation he showed that the heat evolved by the electric current, furnished by a magneto-electric machine, is proportional to the mechanical energy expended; and that the work done by an electro-magnetic engine is derived from the work of chemical affinity in the battery, work which would otherwise be evolved in the form of heat. From these facts he drew the conclusion, "That the quantity of heat capable of increasing the temperature of a lb. of water by one degree

Digitized by Google

of Fahrenheit's scale, is equal to, and may be converted into, a mechanical force capable of raising 838 lb. to the perpendicular height of one foot." In a subsequent paper, read before the Royal Society in 1844 (Phil. Mag. [3] xxvi. 375, 379), he showed that the heat absorbed and evolved by the rarefaction and condensation of air is proportional to the amount of mechanical energy evolved and absorbed in those operations, and obtained a numerical result closely agreeing with that of the electro-magnetic experiments just referred to. In 1845 and 1847 (*ibid.* xxvii. 205; and xxxi. 173) he determined the heat evolved by the friction of water, sperm-oil, and mercury, and obtained the numbers 781·5, 782·1, and 787·6, by experiments on these liquids respectively, as representing the number of foot-pounds which is equivalent to the heat required to raise the temperature of 1 lb. of water 1° Fahrenheit.

Still more elaborate and careful experiments were made by Joule, in 1849 (Phil. Trans. 1850, p. 61; Chem. Soc. Qu. J. iii. 316), upon the friction of water, mercury, and cast-iron, by a method similar to that adopted in those last mentioned. The apparatus employed in this investigation, for the experiments upon water, consisted of a brass paddle-wheel furnished with eight sets of revolving vanes, working between four sets of stationary vanes. This revolving apparatus, of which *fig.* 549 shows a vertical, and *fig.* 550 a horizontal section, was firmly fitted into a copper vessel (see *fig.* 551) containing water, in the lid of which were two necks, one for the axis to revolve in without touching, the other for the insertion of a thermometer. A similar apparatus, but made of iron, and of smaller size, having six rotatory and eight sets of stationary vanes, was used for the experiments on the friction of mercury. The apparatus for the friction of cast-iron consisted of a vertical axis, carrying a bevelled cast-iron wheel, against which a bevelled wheel was pressed by a lever. The wheels were enclosed in a cast-iron vessel filled with mercury, the axis passing through the lid. In each apparatus motion was given to the axis by the descent of leaden weights *w* (*fig.* 551) suspended by strings from the axes of two wooden pulleys, one of

Fig. 549.

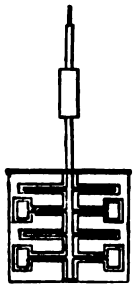


Fig. 550.

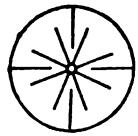

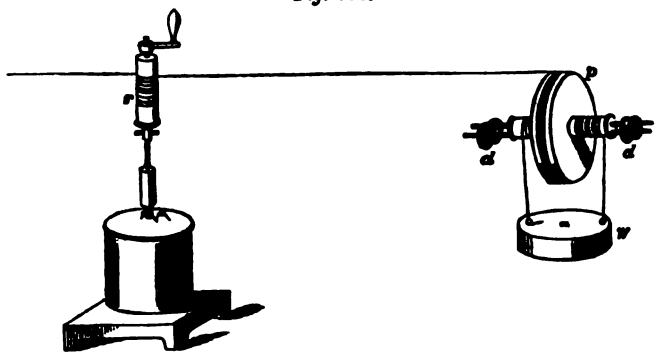

Fig. 551.

which is shown at *p*, their axes being supported on friction-wheels *d d*, and the pulleys were connected by fine twine with a wooden roller *r*, which, by means of a pin, could be easily attached to or removed from the friction apparatus.

The mode of experimenting was as follows: The temperature of the frictional apparatus having been ascertained, and the weights wound up, the roller was fixed to the axis, and the precise height of the weights ascertained; the roller was then set at liberty, and allowed to revolve till the weights touched the floor. The roller was then detached, the weights wound up again, and the friction renewed. This having been repeated twenty times, the experiment was concluded with another observation of the temperature of the apparatus. The mean temperature of the apartment was ascertained by observations made at the beginning, middle, and end of each experiment. Corrections were made for the effects of radiation and conduction; and, in the experiments with water, for the quantities of heat absorbed by the copper vessel and the paddle-wheel. In the experiments with mercury and cast-iron, the heat-capacity

Digitized by Google

of the entire apparatus was ascertained by observing the heating effect which it produced on a known quantity of water in which it was immersed. In all the experiments corrections were also made for the velocity with which the weights came to the ground, and for the friction and rigidity of the strings. The thermometers used were capable of indicating a variation of temperature as small as $\frac{1}{100}$ of a degree Fahrenheit.

The following table contains a summary of the results obtained by this method; the second column gives the results as they were obtained from weighings made in air; the third column, the same results reduced to weighings in a vacuum.

Material employed.	Equivalent in air.	Equivalent in vacuo.	Mean.
Water . . .	773·640	772·692	772·692
Mercury . . .	773·762	772·814	774·083
	776·303	775·352	
Cast-iron . . .	776·997	776·045	774·987
	774·880	774·930	

In the experiments with cast-iron, the friction of the wheels produced a considerable vibration of the frame-work of the apparatus, and a loud sound; it was therefore necessary to make allowance for the quantity of force expended in producing these effects. The number 772·692, obtained by the friction of water, is regarded as the most trustworthy; but even this may be a little too high; because even in the friction of fluids it is impossible entirely to avoid vibration and sound. The conclusions deduced from these experiments are:

1. *That the quantity of heat produced by the friction of bodies, whether solid or liquid, is always proportional to the force expended.*

2. *That the quantity of heat capable of increasing the temperature of* 1 *lb. of water (weighed in vacuo, and between* 55° *and* 60° F.) *by* 1° F., *requires for its evolution the expenditure of a mechanical force represented by the fall of* 772 *lbs. through the space of* 1 *foot.*

Or, the heat capable of increasing the temperature of 1 *gramme of water by* 1° C., *is equivalent to a force represented by the fall of* 423·55 *grammes through the space of* 1 *metre. This is consequently the equivalent of "a unit of heat."*

Since, in consequence of the researches that have been mentioned, the attention of scientific men has been prominently called to the mutual equivalence of heat and work, several investigations have been made, either for the express purpose of ascertaining the numerical ratio expressing that equivalence, or involving determinations from which that ratio can be calculated. In the following table, taken from Verdet's *Exposé de la Théorie Mécanique de la Chaleur* (Paris, 1863), the most trustworthy determinations of the mechanical equivalent of heat are put together. The numbers here given represent the number of kilogramme-metres which is equivalent to 1 kilogramme-degree centigrade, or the number of gramme-metres which is equivalent to 1 gramme-degree.

Table of determinations of the Mechanical Equivalent of Heat.

Nature of the phenomenon whence the determination is drawn.	Philosophers who have indicated the theoretical principle of the determination.	Philosophers who have supplied the experimental data.	Mechanical equivalent.
General properties of air . .	Mayer. Clausius.	V. Regnault. Moll and van Beek.	426

Dynamical Theory of Heat.

For very long, two rival theories have been held regarding the nature of heat: on the one hand, heat has been viewed as having a material existence, though differing from ordinary matter in being without weight, and in other respects; on the other hand, it has been regarded as a state or condition of ordinary matter, and generally as a condition of motion. From the latter part of the last century, until the modern researches upon the mechanical equivalent, the former view had by far the greater number of adherents. Its popularity may be traced chiefly to the teaching of Black and Lavoisier. By the former of these philosophers, the various capacities for heat, or specific heats, of different bodies, seem to have been regarded as analogous to the various proportions of the same acid required to neutralise equal quantities of different bases; while the solid, liquid, and gaseous states were explained by him as representing so many distinct proportions in which heat was capable of combining with ordinary matter. Very similar views were advocated by Lavoisier: he regarded all gases as compounds of a base characteristic of each, with *caloric*, and supposed that when, as the result of chemical action, they assumed the liquid or solid state, this caloric was set free and appeared as sensible heat. Caloric was thus the physical representative of phlogiston, in the same way as oxygen was its chemical representative: the physical portion of the phenomena previously attributed to dephlogistication, being regarded by Lavoisier as caused by the liberation of caloric, just as the chemical portion was explained by him as combination with oxygen. Thus he uniformly speaks (*Traité élémentaire de Chimie*) of the "decomposition" of oxygen-gas by combustible substances, into oxygen (which combines with the combustible) and caloric (which is set free). It is true that Lavoisier guards himself against definitely expressing his belief in the existence of caloric as a substance, but he enumerates it in his list of elements, and seeks to explain all calorimetric phenomena by the analogy of the combination or separation of elementary bodies. Hence, whether regarded by him as necessarily material or not, it became, for his followers, "an imponderable element."

It will be seen that heat was compared to a material substance, by both Black and Lavoisier, in order to explain its then known quantitative relations; and from this point of view, the conception introduced by them had the great advantage of being more easily grasped than any which the advocates of the immaterial nature of heat had to offer in its place. It was much easier to conceive of definite quantities of an exceedingly subtile substance or fluid, than of definite quantities of motion which was itself undefined as to its nature. It was a direct consequence of the material view, that heat should be considered as indestructible and as incapable of being produced, and therefore that the total quantity of heat in the universe should be regarded as at all times the same.

The greatest difficulty which the upholders of the substantial existence of heat had to meet, was its production by mechanical means, a phenomenon of which, as we have seen, several instances were distinctly recognised. Here it was not easy to deny the actual generation of heat, and to explain the effects as depending merely on its altered distribution. Nevertheless, the evolution of heat by friction and percussion was generally considered, by the advocates of the material view, as in some way resulting from a diminution in the capacities for heat of the bodies operated upon; and this explanation derived considerable support from the remark, made by Black, that a piece of soft iron, which has been once made red hot by hammering (see p. 119), cannot be so heated a second time until it has been heated to redness in a fire and allowed to cool. In this case, certainly, it seemed as though the hammering forced out heat from the mass of iron, like water from a sponge, and that a fresh supply was taken up when the iron was put in the fire. But, as has been shown already, this explanation did not satisfy Rumford, who, in the investigation described above, made direct experiments upon the specific heat of the chips of metal detached by the friction, and found it to be identical with that of brass under ordinary circumstances. An experiment which proved, if possible, still more decisively, that the heat generated by friction cannot be ascribed to a diminution in the specific heats of the substances, was made by Davy, in 1799, the year following the publication of Rumford's researches. Davy arranged two pieces of ice, so that they could be caused to rub against each other under the exhausted receiver of an air-pump, but so that it was impossible for heat to be imparted to them by conduction, and found that by friction they were rapidly converted into water, that is to say, into a liquid whose specific heat was twice as great as that of ice. From this experiment Davy drew the same conclusion that Rumford had drawn from his own results, and expressed himself in very similar terms:—"The immediate cause of the phenomena of heat then is motion, and the laws of its communication are precisely the same as the laws of the communication of motion." (*Elements of Chemical Philosophy*, London, 1812, pp. 94, 95.) Similar views were very forcibly

Digitized by Google

advocated by Dr. Thomas Young in his *Lectures on Natural Philosophy;* but, by the majority of scientific men, facts such as we have been referring to, though recognised as difficulties in the way of the material theory of heat, were not allowed to cause its rejection. The ease and apparent precision with which the quantitative phenomena of latent and specific heat could be explained, or at least expressed, upon this theory, still caused it to be generally preferred to one which gave a less definite and, as it seemed, more hypothetical explanation of these phenomena. The mechanical, or dynamical theory, which regarded heat as consisting in a state of molecular motion, cannot be said to have been definitely established until it also was made quantitative,—until it was shown that exact numerical laws regulated the production of heat by work or of work by heat, equally with its production during solidification, or disappearance during fusion. This, as we have seen, was effectually accomplished by Joule, and chiefly as the result of his investigations and of others conducted in the same spirit, philosophers have now been compelled to extend their ideas of quantity from matter to energy, and thus has arisen the new science of Energetics, or the quantitative study of the transformations of energy (as chemistry is the quantitative study of the transformation of matter), comprehending and uniting all the different branches of physical science.

We cannot attempt to give anything like an adequate idea of the state of development which the mechanical theory of heat has now reached; but, in order to illustrate the general nature of the theory, and to show in what sort of way the conception that "heat is motion" has been applied to the explanation of such phenomena as have formed the subject of this article, we give here an outline of the view of the constitution of gases which this theory affords, first put forward, in its present form, by Joule (see Ann. Ch. Phys. [3] l. 381) and subsequently developed by Krönig (Pogg. Ann. xcix. 315) and Clausius (*ibid.* 353), and of the explanation of the relations existing between solids, liquids, and gases, which has been deduced from it by the last-named philosopher. The account which follows, of these applications of the dynamical theory, is taken from Watts's Supplement to *Graham's Elements of Chemistry.* It will be seen that the explanations of phenomena which this theory affords, are at least equally definite with those which can be given upon the view of the material nature of heat.

First, then, it is assumed that the particles of all bodies are in constant motion, and that this motion constitutes heat, the kind and quantity of motion varying according to the state of the body, whether solid, liquid, or gaseous.

In gases, the molecules—each molecule being an aggregate of atoms—are supposed to be constantly moving forward in straight lines, and with a constant velocity, till they impinge against each other or against an impenetrable wall. This constant impact of the molecules produces the expansive tendency or elasticity, which is the peculiar characteristic of the gaseous state. The rectilinear movement is not, however, the only one with which the particles are affected. For the impact of two molecules, unless it takes place exactly in the line joining their centres of gravity, must give rise to a rotatory motion; and, moreover, the ultimate atoms of which the molecules are composed may be supposed to vibrate within certain limits, being, in fact, thrown into vibration by the impact of the molecules. This vibratory motion is called, by Clausius, *the motion of the constituent atoms* (*Bewegungen der Bestandtheile*). The total quantity of heat in the gas is made up of the progressive motion of the molecules, together with the vibratory and other motions of the constituent atoms; but the progressive motion alone, which is the cause of the expansive tendency, determines the *temperature.* Now, the outward pressure exerted by the gas against the containing envelope arises, according to our hypothesis, from the impact of a great number of gaseous molecules against the sides of the vessel. But at any given temperature, that is, with any given velocity, the number of such impacts taking place in a given time, must vary inversely as the volume of the given quantity of gas; hence *the pressure varies inversely as the volume or directly as the density,* which is Boyle's law.

When the volume of the gas is constant, the pressure resulting from the impact of the molecules is proportional to the sum of the masses of all the molecules multiplied into the squares of their velocities, in other words, to the so-called *vis viva* or *living force* of the progressive motion.

If, for example, the velocity be doubled, each molecule will strike the sides of the vessel with a two-fold force, and its number of impacts in a given time will also be doubled; hence the total pressure will be quadrupled.

Now we know that when a given quantity of any perfect gas is maintained at a constant volume, it tends to expand by $\frac{1}{273}$ of its bulk at zero for each degree centigrade. Hence the pressure or elastic force increases proportionally to the temperature reckoned from -273° C.; that is to say, to the absolute temperature. Consequently, the *absolute temperature is proportional to the* vis viva *of the progressive motion.*

Suppose a vessel of the form of a rectangular parallelopiped, the lengths of whose sides are x, y, z, to contain n gas-molecules, each having the mass m. Suppose, also, the space enclosed by this vessel to be divided into $\frac{n}{6}$ equal cubes; and at a given instant let there be in each of these cubes six gas-molecules, moving severally in the directions $+x$, $-x$, $+y$, $-y$, $+z$, $-z$, and with the common velocity c. Let it also be supposed that the molecules exert no mutual action upon each other, but pass without hindrance from side to side of the vessel. It is required to determine the pressure, which the gas exerts against one of the sides, yz, of the vessel. The pressure arising from the impact of a single gas-molecule is mca, if a denote the number of impacts which take place in a unit of time. Now, a molecule moving at right angles to yz, or parallel to x, strikes against yz every time that it passes over the space $2x$; therefore $a = \frac{c}{2x}$.

To find the total pressure P upon yz, the quantity, mca, must be multiplied by the number of molecules which move parallel to x, which number, since two atoms out of every six are parallel to x, is $\frac{n}{3}$. Hence $P = m.c.\frac{c}{2x}.\frac{n}{3}$. And the pressure p upon a unit of surface of the side yz, is $p = m.c.\frac{c}{2x}.\frac{n}{3}.\frac{1}{yz}$; or if we put $xyz = v$, and leave out the constant factor:

$$p = \frac{nmc^2}{v}.$$

This expression shows that the pressure exerted upon a unit of surface is the same for each side of the vessel; also, that the pressure is inversely in proportion to the volume of the gas, which is Boyle's law.

The product, mc^2, or the *vis viva* of an atom, is the expression of the temperature reckoned from the absolute zero, or —273° C.

If, in the preceding value of p, we put $mc^2 = \tau$, we have

$$p = \frac{n\tau}{v},$$

that is to say, when the volume is constant, the pressure varies directly as the absolute temperature. (Krönig.)

If, for two different gases, we suppose p, τ and v, equal, it follows from this expression, that n also must be the same for both. That is to say, at the same temperature and pressure, equal volumes of different gases contain the same number of molecules. Hence also, the mass, m, of a molecule is proportional to the specific gravity, s, of the gas: or, the molecular weights of different substances are proportional to their vapour-densities (taken at temperatures at which the vapours have the properties of true gases).

Clausius, taking into consideration the *vis viva* of the vibratory and rotatory movements as well of the progressive movements, arrives at the expression, $p = \frac{nmc^2}{3v}$, or $pv = \frac{nmc^2}{3}$, which differs from that of Krönig only by a constant factor.

From this equation, it is possible to deduce the mean value of the absolute progressive velocity of the molecules of any gas for any given temperature. It gives, in fact, directly,

$$c^2 = \frac{3pv}{nm},$$

or, putting q for the weight of the gas, and g for the force of gravity,—

$$c^2 = \frac{3gpv}{q},$$

an expression which contains only numerically determinable quantities. Denoting by ρ the density of the gas compared with that of air at 0°, introducing into the formula the known values of the weight of a litre of air and of the force of gravity, taking p equal to the normal atmospheric pressure, and denoting the absolute temperature by τ, the value of c, expressed in metres, becomes

$$c = 485\sqrt{\frac{\tau}{273\rho}},$$

Digitized by Google

which gives at 0° C., for Oxygen $c = 461$ metres per second
„ Nitrogen $c = 492$ „ „
„ Hydrogen $c = 1844$ „ „

Hence, the velocity of translation of the molecules of a gas is inversely as the square-root of its density, which gives Graham's law of the diffusion of gases, and the law of their velocity of entrance into a vacuum.

Moreover, as the motions of the constituent particles of a gas depend on the manner in which its atoms are united, it follows that in any given gas the different motions must be to one another in a constant ratio; and, therefore, the *vis viva* of the progressive motion must be an aliquot part of the entire *vis viva* of the gas; hence also the absolute temperature is proportional to the total *vis viva* arising from all the motions of the particles of the gas.

From this it follows that the quantity of heat which must be added to a gas of constant volume in order to raise its temperature by a given amount, is constant and independent of the temperature. In other words, the specific heat of a gas referred to a given volume is constant, a result which agrees with the experiments of Regnault, mentioned at p. 34. This result may be otherwise expressed, as follows: *The total* vis viva *of the gas is to the* vis viva *of the progressive motion of the molecules, which is the measure of the temperature, in a constant ratio.* This ratio is different for different gases, and is greater as the gas is more complex in its constitution; in other words, as its molecules are made up of a greater number of atoms. The specific heat referred to a constant pressure is known to differ from the true specific heat only by a constant quantity (see p. 42).

The relations just considered between the pressure, volume and temperature of gases, presuppose, however, contain conditions of molecular constitution, which are, perhaps, never rigidly fulfilled; and accordingly, the experiments of Magnus and Regnault (p. 48) show that gases do exhibit slight deviations from Gay-Lussac and Boyle's laws. What the conditions are which strict adherence to these laws would require, will be better understood by considering the differences of molecular constitution which must exist in the solid, liquid, and gaseous states.

A movement of molecules must be supposed to exist in all three states. In the *solid state*, the motion is such that the molecules oscillate about certain positions of equilibrium, which they do not quit, unless they are acted upon by external forces. This vibratory motion may, however, be of a very complicated character. The constituent atoms of a molecule may vibrate separately; the entire molecules may also vibrate as such about their centres of gravity, and the vibrations may be either rectilinear or rotatory. Moreover, when extraneous forces act upon the body, as in shocks, the molecules may permanently alter their relative positions.

In the *liquid state*, the molecules have no determinate positions of equilibrium. They may rotate completely about their centres of gravity, and may also move forward into other positions. But the repulsive action arising from the motion is not strong enough to overcome the mutual attraction of the molecules and separate them completely from each other. A molecule is not permanently associated with its neighbours, as in the solid state; it does not leave them spontaneously, but only under the influence of forces exerted upon it by other molecules, with which it then comes into the same relation as with the former. There exists, therefore, in the liquid state, a vibratory, rotatory and progressive movement of the molecules, but so regulated, that they are not thereby forced asunder, but remain within a certain volume without exerting any outward pressure.

In the *gaseous* state, on the other hand, the molecules are removed quite beyond the sphere of their mutual attractions, and travel onward in straight lines according to the ordinary laws of motion. When two such molecules meet, they fly apart from each other, for the most part, with a velocity equal to that with which they came together. The perfection of the gaseous state, however, implies: 1. That the space actually occupied by the molecules of the gas be infinitely small in comparison with the entire volume of the gas.—2. That the time occupied in the impact of a molecule, either against another molecule or against the sides of the vessel, be infinitely small in comparison with the interval between any two impacts.—3. That the influence of the molecular forces be infinitely small. When these conditions are not completely fulfilled, the gas partakes more or less of the nature of a liquid, and exhibits certain deviations from Gay-Lussac and Boyle's laws. Such is, indeed, the case with all known gases; to a very slight extent with those which have not yet been reduced into the liquid state; but to a greater extent with vapours and condensable gases, especially near the points of condensation.

Let us now return to the consideration of the liquid state. It has been said that the molecule of a liquid, when it leaves those with which it is associated, ultimately

Digitized by Google

takes up a similar position with regard to other molecules. This, however, does not preclude the existence of considerable irregularities in the actual movements. Now, at the surface of the liquid, it may happen that a particle, by a peculiar combination of the rectilinear, rotatory and vibratory movements, may be projected from the neighbouring molecules with such force as to throw it completely out of their sphere of action, before its projectile velocity can be annihilated by the attractive force which they exert upon it. The molecule will then be driven forward into the space above the liquid, as if it belonged to a gas, and that space, if originally empty, will, in consequence of the action just described, become more and more filled with these projected molecules, which will comport themselves within it exactly like the molecules of a gas, impinging and exerting pressure upon the sides of the envelope. One of these sides, however, is formed by the surface of the liquid, and when a molecule impinges upon this surface, it will, in general, not be driven back, but retained by the attractive forces of the other molecules. A state of equilibrium, not static, but dynamic, will therefore be attained when the number of molecules projected in a given time into the space above, is equal to the number which in the same time impinge upon and are retained by the surface of the liquid. This is the process of vaporisation. The density of the vapour required to ensure the compensation just mentioned, depends upon the rate at which the particles are projected from the surface of the liquid, and this again upon the rapidity of their movement within the liquid, that is to say, upon the temperature. It is clear, therefore, that the density of a saturated vapour must increase with the temperature.

If the space above the liquid is previously filled with a gas, the molecules of this gas will impinge upon the surface of the liquid, and thereby exert pressure upon it; but as these gas-molecules occupy but an extremely small proportion of the space above the liquid, the particles of the liquid will be projected into that space almost as if it were empty. In the middle of the liquid, however, the external pressure of the gas acts in a different manner. There also it may happen that the molecules may be separated with such force as to produce a small vacuum in the midst of the liquid. But this space is surrounded on all sides by masses which afford no passage to the disturbed molecules; and in order that they may increase to a permanent vapour-bubble, the number of molecules projected from the inner surface of the vessel must be such as to produce a pressure outwards, equal to the external pressure tending to compress the vapour-bubble. The boiling point of the liquid will, therefore, be higher as the external pressure is greater.

According to this view of the process of vaporisation, it is possible that vapour may rise from a solid as well as from a liquid; but it by no means necessarily follows that vapour must be formed from all bodies at all temperatures. The force which holds together the molecules of a body may be too great to be overcome by any combination of molecular movements, so long as the temperature does not exceed a certain limit.

The *production* and *consumption of heat* which accompany changes in the state of aggregation, or of the volume of bodies, are easily explained, according to the preceding principles, by taking account of the *work* done by the acting forces. This work is partly external to the body, partly internal. To consider first the internal work:

When the molecules of a body change their relative positions, the change may take place either in accordance with or in opposition to the action of the molecular forces existing within the body. In the former case, the molecules, during the passage from one state to the other, have a certain velocity imparted to them, which is immediately converted into heat; in the latter case, the velocity of their movement, and consequently the temperature of the body, is diminished. In the passage from the solid to the liquid state, the molecules, although not removed from the spheres of their mutual attractions, nevertheless change their relative positions in opposition to the molecular forces, which forces have, therefore, to be overcome. In evaporation, a certain number of the molecules are completely separated from the remainder, which again implies the overcoming of opposing forces. In both cases, therefore, work is done, and a certain portion of the *vis viva* of the molecules, that is, of the heat of the body, is lost. But when once the perfect gaseous state is attained, the molecular forces are completely overcome, and any further expansion may take place without internal work, and, therefore, without loss of heat, provided there is no external resistance.

But in nearly all cases of change of state or volume, there is a certain amount of external resistance to be overcome, and a corresponding loss of heat. When the pressure of a gas, that is to say, the impact of its atoms, is exerted against a movable obstacle, such as a piston, the molecules lose just so much of their moving power as they have imparted to the piston, and, consequently, their velocity is diminished and the temperature lowered. On the contrary, when a gas is compressed by the motion of a piston, its molecules are driven back with greater velocity than that with which they impinged on the piston, and, consequently, the temperature of the gas is raised.

Digitized by Google

When a liquid is converted into vapour, the molecules have to overcome the atmospheric pressure or other external resistance, and, in consequence of this, together with the internal work already spoken of, a large quantity of heat disappears, or is rendered *latent*, the quantity thus consumed being to a considerable extent affected by the external pressure. The liquefaction of a solid not being attended with much increase of volume, involves but little external work; nevertheless the atmospheric pressure does influence, to a slight amount, both the latent heat of fusion and the melting point.

We must here mention, in conclusion, a very remarkable consequence of the relation of mutual convertibility which, as we have endeavoured to show, exists between heat and other forms of energy. "Professor William Thomson has pointed out the fact, that there exists (at least in the present state of the known world) a predominating tendency to the conversion of all the other forms of physical energy into heat, and to the uniform diffusion of all heat throughout all matter. The form in which we generally find energy originally collected, is that of a store of chemical power, consisting of uncombined elements. The combination of these elements produces energy in the form known by the name of electric currents, part only of which can be employed in analysing compounds, and thus reconverted into a store of chemical power; the remainder is necessarily converted into heat: a part only of this heat can be employed in analysing compounds, or in reproducing electric currents. If the remainder of the heat be employed in expanding an elastic substance, it may be entirely converted into visible motion, or into a store of visible mechanical power (by raising weights, for example), provided the elastic substance is enabled to expand until its temperature falls to the point which corresponds to the absolute privation of heat; but unless this condition be fulfilled, a certain proportion only of the heat, depending upon the range of temperature through which the elastic body works, can be converted, the rest remaining in the state of heat. On the other hand, all visible motion is of necessity ultimately converted entirely into heat by the agency of friction. There is, then, in the present state of the known world, a tendency towards the conversion of all physical energy into the sole form of heat.

"Heat, moreover, tends to diffuse itself uniformly by conduction and radiation, until all matter shall have acquired the same temperature.

"There is, consequently, Professor Thomson concludes, so far as we understand the present condition of the universe, a tendency towards a state in which all physical energy will be in the state of heat, and that heat so diffused that all matter will be at the same temperature; so that there will be an end of all physical phenomena.

"Vast as this speculation may seem, it appears to be soundly based on experimental data, and to represent truly the present condition of the universe, so far as we know it." (Rankine, Phil. Mag. [4] iv. 359.)

*** For *Radiation and Conduction of Heat*, see RADIATION.

APPENDIX.

The following table gives the temperatures measured by the air-thermometer, at which, according to Regnault's experiments (Mém. Acad. Sciences, xxvi. 658), the vapours of the liquids enumerated in it exert a pressure equal to that of 760 millimetres of mercury:—

Substance.	Temperature	Substance.	Temperature.
Nitrous oxide	− 87·90°	Chloride of silicon	56·81°
Carbonic anhydride	− 78·2	Chloroform	60·16
Sulphydric acid	− 61·8	Methylic alcohol	66·78
Ammonia	− 38·5	Trichloride of phosphorus	73·80
Chlorine	− 33·6	Perchloride of carbon (CCl^4)	76·50
Chloride of methyl	− 23·73	Alcohol	78·26
Oxide of methyl	− 23·65	Benzene	80·36
Sulphurous anhydride	− 10·08	Bromide of ethylene	131·60
Chloride of ethyl	+ 12·50	Oil of turpentine	159·15
Chloride of cyanogen	12·66	Oxalate of methyl	164·20
Chloride of boron	18·23	Oil of lemons	174·80
Ether	34·97	Mercury	357·25
Bromide of ethyl	38·37	Sulphur	448·00
Sulphide of carbon	46·20		

The next table, also from Regnault's experiments (*Op. cit.* pp. 327–332), gives the specific heats of various substances in different states of aggregation. Where, in the column indicating the temperature, some particular degree is given, the number repre-

Digitized by Google

senting the specific heat is the *elementary* specific heat at that degree of temperature,—that is, the quantity of heat required to cause a *very small* alteration of temperature in one gramme of the substance, compared with the quantity required to cause a like infinitesimal alteration of temperature in 1 gramme of water. When an interval of temperature is given, the specific heat is the mean specific heat within that interval:—

HEAVY SPAR. *Barytes. Native Sulphate of Barium.* $Ba''SO^4$.—This mineral occurs in crystals belonging to the trimetric system. Ratio of axes $a : b \cdot c$, 0·6206 : 1 : 0·7618; $\infty\breve{P}$: ∞P in the macrodiagonal principal section = 63° 38′; $\infty\breve{P}2$: $\infty\breve{P}2$ in the same = 102° 18′; $\breve{P}\infty$: $\breve{P}\infty$ in the basal section = 74° 36′; $\breve{P}\infty$: $\breve{P}\infty$ in the same = 100° 40′. *Figs.* 552–556 represent frequently occurring combinations.

Fig. 552.

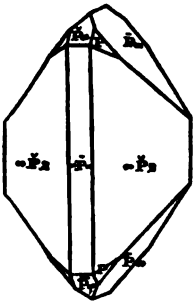

Fig. 553.

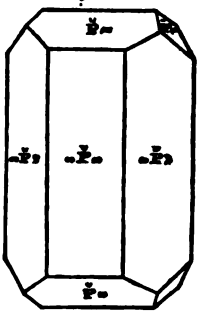

Fig. 554.

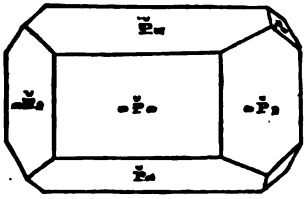

Fig. 555.

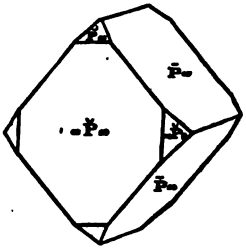

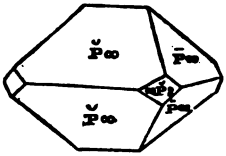

Fig. 556.

The crystals are sometimes prismatically elongated in the direction of one of the axes (*figs. 553, 554*), and sometimes reduced to the tabular form by shortening in one direction (see CRYSTALLOGRAPHY, ii. 149). Cleavage very distinct, parallel to $\infty\breve{P}\infty$. The mineral occurs also massive, with fibrous or laminar structure; also granular. Hardness 2·5 to 3·5. Specific gravity 4·3 to 4·72. Colour white, or inclining to grey, blue, green, yellow, red or brown. Streak white. Lustre splendent, between resinous and pearly. Transparent, exhibiting various degrees of translucency down to perfect opacity. It is sometimes fœtid when rubbed; an impure variety called *hepatite* exhibits this property in a peculiar degree. It decrepitates before the blowpipe, and fuses with difficulty at the edges only. In the inner flame it is reduced to sulphide of barium, and then gives off sulphydric acid when treated with an acid.

Pure heavy spar contains 34·33 per cent. SO^3 and 65·67 Ba^2O; but the mineral generally also contains small quantities of alumina, oxide of iron, silica, and carbonate of calcium. Sulphate of strontium is also a common ingredient. The variety called *calstronbaryte* contains 1 at. lime and 1 at. strontium to 9 at. barium.

It is a very abundant mineral, generally occurring in metalliferous veins, as in the lead-mines of Durham, Cumberland, and Westmoreland. It occurs also in secondary limestones, sometimes in distinct veins, and often in crystals associated with cœlestin and calcspar. In Staffordshire and Derbyshire is found an opaque, massive variety called *cawk*, having an earthy appearance and dirty white colour. On the continent of Europe it is found chiefly at Felsöbanya and Kremnitz, at Freiberg, Marienberg, Clausthal, and Przibram, and at Roya and Roure in Auvergne. Rounded masses, composed of divergent columnar particles, occur at Mount Paterno, near Bologna, hence called *Bolognese stone*. At Freiberg, in Saxony, a variety occurs composed of indistinct prismatic crystals, having a pearly lustre, called *Stangenspath* by Werner. (For the American localities, see Dana, ii. 367.)

Heavy spar occurs altered to calcspar, spathic iron, cerusite, quartz, limonite red iron-ore, pyrites, psilomelane, göthite.

The white varieties of heavy spar are ground and used as a white paint, sometimes alone, but more generally mixed with white lead, the heavy spar alone not possessing sufficient opacity to form a good pigment.

Digitized by Google

HEBETIN. Anhydrous silicate of zinc. (See WILLEMITE.)

HEDENBERGITE. A black variety of augite, containing a large quantity of iron, little or no magnesia, and no alumina. Specific gravity 3·5. Found chiefly at Tunaberg, in Sweden.

HEDERA HELIX. *Ivy.*—The seeds of this plant contain a nitrogenous substance resembling emulsin, also fat, two peculiar acids, sugar, a small quantity of pectin, and inorganic salts. From the fresh seeds, ether extracts a green oil, containing a solid and a liquid fat. The former is somewhat difficult to saponify, and yields by saponification a fatty acid, which, after repeated crystallisation from alcohol, melts at a temperature not above 30°, and forms a silver salt containing from 27·4 to 27·6 silver (Posselt). The acids contained in ivy-seeds are described in the next article.

HEDERIC ACID. An acid contained, according to Posselt (Ann. Ch. Pharm. lxix. 62) in the seeds of ivy (*Hedera helix*). It is obtained by treating the seeds with ether to remove fatty matters, and boiling the residue with alcohol, which dissolves the acid, and deposits it, after concentration, in needles or delicate scales, colourless, and insoluble in water and in ether. The acid is inodorous, but possesses in a high degree the acrid taste of ivy-seeds. It gives by analysis, 66·6 per cent. C, and 9·5 H; its rational formula is unknown. It gives off 5·42 percent. water at 100°, and chars without melting at a higher temperature. In contact with strong sulphuric acid it assumes a fine purple colour.

Hederic acid decomposes carbonates, and forms gelatinous salts, most of which are insoluble in water, but soluble in alcohol. Even the *potassium*- and *ammonium*-salts dissolve but sparingly in water, and are deposited as gelatinous precipitates when the solutions are left at rest. The *silver*-salt is deposited from boiling alcohol in white crystals.

Ivy-seeds likewise contain another acid, the presence of which greatly impedes the purification of hederic acid. This acid is uncrystallisable; soluble in water, alcohol and ether; forms soluble yellow salts; precipitates lead-salts, reduces nitrate of silver, and colours ferric salts green. It appears to belong to the family of the tannic acids.

HEDERINE. An alkaloïd said to exist in ivy-seeds. (Vandamme and Chevallier, J. Chim. méd. [2] vi. 581.)

HEDYPHANE. A variety of green lead-ore in which the lead is partly replaced by calcium. Found at Långsbanshytta, in Sweden; also called MIMETENE (*q. v.*)

HELENENE. An oily hydrocarbon produced by distilling helenin with phosphoric anhydride. After rectification, it is yellowish, lighter than water, and has a faint odour resembling that of acetone. Boils between 285° and 295°. Gives by analysis 89·0 to 89·8 C, and 10·1 to 10·4 H, agreeing nearly with the formula $C^{19}H^{28}$ (89·8 C, and 10·2 H). Its formation may perhaps be represented by the equation:

$$C^{21}H^{30}O^{3} = C^{19}H^{28} + H^{2}O + 2CO.$$

The evolution of carbonic oxide has not, however, been actually observed.

Helenene heated with fuming sulphuric acid is converted into *sulpho-helenic* acid, the barium-salt of which contains 17·75 per cent. barium.

HELENIN. $C^{21}H^{30}O^{3}$.—A crystalline substance existing in the root of elecampane (*Inula helenium*); it was first observed by Geoffroy, afterwards examined by Dumas, and more especially by Gerhardt (*Traité*, iv. 296). It may be obtained by distilling the root with water, or better by boiling it with alcohol of 80 per cent.; filtering the solution at the boiling heat, and mixing it with three or four times its volume of cold water. The liquid, after twenty-four hours, deposits helenin in long quadrilateral prisms.

Helenin is perfectly colourless, and has very little taste or odour. It is insoluble in water, but very soluble in alcohol and ether. It melts at 72°, and boils between 275° and 280°, decomposing more or less at the same time.

Helenin is not attacked by alkalis in aqueous or alcoholic solution; but when heated with potash-lime, it yields a resinous compound, which remains combined with the potash. Strong sulphuric acid dissolves it with blood-red colour, forming a conjugated acid. Hydrochloric acid gas is absorbed by it in large quantity.

By *chlorine*, with the aid of heat, it is converted into *chlorhelenin*, perhaps $C^{21}H^{24}Cl^{4}O^{3}$; and by nitric acid into *nitrohelenin*. Phosphoric anhydride converts it into *helenene*.

HELIANTHIC ACID. $C^{14}H^{9}O^{7}, HO$?—An acid obtained from sunflower seeds, belonging, according to Ludwig and Kromayer, to the tannic acid group. By boiling with moderately dilute hydrochloric acid in a stream of hydrogen, it is resolved into fermentable sugar, and an acid violet colouring matter.

HELIANTHUS ANNUUS. *The Sunflower.*— The peeled seeds of this plant

Digitized by Google

contain, according to Ludwig and Kromayer (Arch. Pharm. [2] xcix. 1, 285): 1. Helianthic acid.—2. A *fat oil*, amounting to 40 per cent. of the peeled seeds.—3. A small quantity of *fermentable sugar*, uncrystallisable, and capable of reducing cupric oxide, only when the latter is present in considerable quantity in alkaline solution.—4. A substance soluble in alcohol, precipitated from this solution by ether in the form of a syrup, not directly fermentable, and not capable of reducing cupric oxide in alkaline solution, but convertible by boiling, either alone or with acids, into a substance which reduces cupric to cuprous oxide, and perhaps constituting a link between inulin and sugar.—5. *Legumin*.—6. A substance perhaps identical with inulin, insoluble in cold water and alcohol, and converted by boiling with dilute acids into a body which reduces cupric to cuprous oxide.—7. Mulders' horny vegetable albumin (a body resembling cellulose, soluble in strong sulphuric acid, and precipitable from this solution by water).—8. A mixture resembling cerebrin, and another resembling oleophosphoric acid.—9. Cellulose.

The nitrogenous substance, which is soluble in boiling alcohol, and remains as a gelatinous mass when the alcohol is distilled off, appears to be a compound of helianthic acid with a protein-substance, accompanied by a soapy compound.

The peeled seeds dried in the air at mean temperatures yielded 4·2 per cent. ash, of which 3·8 pts. were insoluble, and 0·4 soluble in water.

HELICIN. $C^{13}H^{16}O^{7}$. (Piria, Ann. Ch. Phys. [3] xiv. 287.)—A body produced by the action of very dilute nitric acid upon salicin:

$$\underset{\text{Salicin.}}{C^{13}H^{18}O^{7}} + O = H^{2}O + \underset{\text{Helicin.}}{C^{13}H^{16}O^{7}};$$

also, together with benzoic acid, by boiling benzo-helicin with magnesia (Piria, Ann. Ch. Pharm. xcvi. 380). To prepare it, 1 pt. of pulverised salicin is mixed with 10 pts. of nitric acid of 20° Bm. (specific gravity 1·157), and the mixture is left to itself in an open vessel. In about 24 hours the salicin is completely dissolved, especially if the mixture be stirred from time to time, and crystals of helicin collect at the bottom of the vessel. They must be pressed between paper and purified by washing with ether till the ether which runs off no longer reddens ferric salts. Salicin yields about two-thirds of its weight of helicin.

Helicin crystallises in small, white, very slender needles containing $\frac{3}{4}$ at. water. It is neutral, slightly bitter, sparingly soluble in cold *water*, dissolves very freely in boiling water; it is soluble also in *alcohol*, but is insoluble in *ether*. At 100° C. it gives off its water of crystallisation, amounting to 4·54 per cent. At 175° it melts, and at a higher temperature gives off vapours of hydride of salicyl. Under the influence of *emulsin*, or of dilute *acids* or *alkalis* at the boiling heat, it is resolved into glucose and hydride of salicyl:

$$\underset{\text{Helicin.}}{C^{13}H^{16}O^{7}} + H^{2}O = \underset{\text{Glucose.}}{C^{6}H^{12}O^{6}} + \underset{\text{Hydride of salicyl.}}{C^{7}H^{6}O^{2}}.$$

At ordinary temperatures, the fixed alkalis and alkaline earths merely increase the solubility of helicin in water.

Benzo-helicin. $C^{20}H^{20}O^{8} = C^{13}H^{13}(C^{7}H^{5}O)O^{7}$.—This compound, which is related to helicin in the same manner as populin to salicin, is obtained by dissolving benzo-salicin (populin) in 10 or 12 times its weight of nitric acid of specific gravity 1·3. It crystallises in tufts of silky needles, which do not give off any water when heated. It dissolves in boiling *water*; and if the first drops of a solution filtered at the boiling heat crystallise on cooling, the crystallisation extends throughout the entire mass; but on again applying heat, and leaving the solution to cool slowly and quietly, it solidifies to a gelatinous pulp.

Benzo-helicin is not decomposed by emulsin, but *alkalis* and *acids* convert it into benzoic acid, hydride of salicyl, and glucose:

$$\underset{\text{Benzo-helicin.}}{C^{20}H^{20}O^{8}} + 2H^{2}O = \underset{\text{Benzoic acid.}}{C^{7}H^{6}O^{2}} + \underset{\text{Hydride of salicyl.}}{C^{7}H^{6}O^{2}} + \underset{\text{Glucose.}}{C^{6}H^{12}O^{6}}.$$

By boiling with *magnesia* (or other bases which do not act upon helicin), it is resolved into benzoic acid and helicin.

Brombelicin, $C^{13}H^{15}BrO^{7}.H^{2}O$, is prepared like chlorhelicin, and exhibits similar reactions, but always separates from solution in the gelatinous form, and when dry, forms a dirty white powder without any appearance of crystallisation.

Chlorhelicin, $C^{13}H^{15}ClO^{7}$, exists in two modifications, which may be distinguished as α and β.

α *Chlorhelicin* is obtained by agitating helicin with water in a vessel filled with chlorine. The product is purified by pressure, washing with cold water, and solution in boiling

Digitized by Google

water, the liquid as it cools either depositing small needles of monohydrated c helicin, $2C^{13}H^{18}ClO^7.H^2O$, or solidifying to an amorphous jelly containing a l quantity of water.

α Chlorhelicin is inodorous, bitter, nearly insoluble in cold *water*, easily solub hot water and in *alcohol*. The crystals contain 3 per cent. water, which is rather than the amount required by the formula just given (2·76 per cent.), the excess bably arising from admixture of a small quantity of gelatinous α chlorhelicin. heated to between 120° and 130°, they give off the whole of their water, and th maining anhydrous α chlorhelicin, when raised to a higher temperature, give vapours of hydride of chlorosalicyl. This product is likewise obtained, together glucose or its products of decomposition, on heating α chlorhelicin with dilute aci *alkalis*, or by treating it with *emulsin*:

$$C^{13}H^{15}ClO^7 + H^2O = C^{13}H^8ClO^2 + C^6H^{12}O^6.$$

β *Chlorhelicin.* When chlorine is passed into an alcoholic solution of helicin, a v granular substance is obtained, which has the composition of α chlorhelicin, b insoluble in water, nearly insoluble in boiling alcohol, and is not decomposed in manner just mentioned by acids, alkalis, or emulsin.

HELICOÏDIN. $C^{26}H^{32}O^{14}$ (Piria, Ann. Ch. Phys. [3] xiv. 292).—This stance, which may be regarded as a compound of helicin and salicin ($C^{13}H^{1}$ $C^{13}H^{18}O^7$), is obtained by treating salicin with nitric acid still more dilute than which is used for the preparation of helicin, viz. of 12° Bm. (specific gravity 1· It may be purified by washing with cold water and crystallisation from boiling w It forms needles resembling those of helicin, and containing $\frac{3}{2}$ at. water ($2C^{26}H^{34}$ $3H^2O$). Under the influence of emulsin it is decomposed similarly to helicin, yiel however, saligenin in addition to glucose and hydride of salicyl:

$$\underset{\text{Helicoïdin.}}{C^{26}H^{34}O^{14}} + 2H^2O = \underset{\text{Glucose.}}{2C^6H^{12}O^6} + \underset{\substack{\text{Hydride}\\\text{of salicyl.}}}{C^7H^6O^2} + \underset{\text{Saligenin.}}{C^7H^8O^2}.$$

Alkalis and acids act in the same manner, the latter, however, converting the salig into saliretin (C^7H^6O) by abstraction of water.

Helicin, salicin, and helicoïdin are related to one another in the same mann quinone, colourless hydroquinone, and green hydroquinone.

HELIOTROPE or *Bloodstone.* A variety of chalcedony, having a deep g colour with blood-red spots. It is used as a gem.

HELIX POMATIA. The *Garden* or *Vineyard Snail.*—The shell and operc of this mollusc have been analysed by B. Wicke (Ann. Ch. Pharm. cxxv. 79), the following results:—

	$CaCO^3$	$MgCO^3$	Earthy Phosphates.	Ferric Phosphate.	SiO^2	Organic Substance.	
Shell .	96·07	0·98	0·85		1·15	0·95	= 10
Operculum .	86·75	0·96	5·36	0·16	0·35	6·42	= 10

W. Wicke (Ann. Ch. Pharm. lxxvii. 224) found in the operculum 94·24 per c carbonate, and 5·73 per cent. phosphate of calcium, together with traces of ferric oxide phosphate of magnesium. He supposes that the phosphate of calcium is contai chiefly in the small nodules which cover the surface of the operculum. Joy (lxxxii. 365) found in the shell, 98·5 per cent. carbonate of calcium and 1·5 org matter, but no phosphoric acid, silicic acid, fluorine, magnesia, or alkalis. Gobley Pharm. [3] xxxiii. 161) found that the shell contained 70 per cent. water, and w dried consisted almost wholly of carbonate of calcium, with small quantities of ea and ferric phosphates, and animal matter.

In the animal itself, Gobley found a peculiar mucus, containing a small quantit carbonate of potassium, which gives it an alkaline reaction, redissolves in water a drying, but loses this property after a while. Gobley also found, besides the s usually occurring in the animal organism, a small quantity of chloride of ammoni a peculiar compound of animal matter with carbonate of calcium, partially solubl water, and traces of iodine. Beneke (Ann. Ch. Pharm. cxii. 249) found in animal, a peculiar fatty substance called myelin, existing also in the brain and ot organs of the higher animals, which swells up in peculiar forms when soaked in wa

HELLEBORINE. An azotised body contained in the root of black helleb (*Helleborus hiemalis*). It is obtained by exhausting the root with alcohol, dilut the extract with a certain quantity of water, which precipitates a resin, and conc trating the filtered liquid.

It forms colourless crystals, having a harsh bitter taste, soluble in water and alcohol, more soluble in ether. The solutions are neutral to test-paper. It is dec posed by heat, also by nitric and sulphuric acids. Heated with potash it gives

Digitized by Google

ammonia. It is not precipitated from its solutions by acetate of lead, chloride of mercury, or iodide of potassium. (W. Bastick, Pharm. J. Trans. xii. 174.)

HELLEFLINTA. Called also *Leelite*. A variety of felspar, occurring at Gryphyttan, in Sweden, having a peculiar waxy lustre and deep flesh-red colour.

HELLENINE and **HELLENIN.** See HELENINE and HELENIN (p. 138).

HELMINTH. A variety of chlorite occurring in felspar and quartz. (Dana, ii. 294).

HELMINTHOLITE. A variety of limestone, generally of a dark colour, and distinguished by the beautiful red and green iridescence of the fossil shells which it contains. It is found in Carinthia, at Halle in the Tyrol, and other localities, and is made into a variety of ornamental articles. (Handw. d. Chem. iii. 848.)

HELVIN. *Tetrahedral Garnet.*—A mineral consisting of silicate of manganese, iron, and glucinum, combined with oxysulphide of manganese. It occurs in regular tetrahedrons. Hardness 6 to 6·5, rather greater than that of felspar. Specific gravity 3·1 to 3·3. Lustre vitreous, inclining to resinous. Colour wax-yellow, inclining to yellowish brown and siskin-green. Streak uncoloured. Subtranslucent. Fracture uneven. On charcoal, in the reducing flame, it melts, with intumescence, to a yellow opaque globule. When finely pulverised it is decomposed by hydrochloric acid, with evolution of sulphydric acid and separation of gelatinous silica.

Analyses: 1, 2. From Saxony, by C. Gmelin (Pogg. Ann. iii. 53). 3. From Norway, by Rammelsberg (*Mineralchemie*, p. 700):

	1	2	3
Silica	35·27	33·26	33·13
Sulphur	—	5·05	5·71
Alumina	1·44	12·03	11·46
Glucina	8·03		
Ferrous oxide	8·00	5·56	4·00
Manganous oxide	42·12	41·76	49·12
Loss by ignition	—	1·15	—
	94·86	98·81	103·42

Hence Rammelsberg deduces the formula

$$2(Mn; Fe)''S \,.\, 3[2(Mn; Fe)''O.2SiO^2 + 2G''O.SiO^2]$$

which is reducible to the form of an orthosilicate united with a protosulphide,

$$3M^4SiO^4.2M^2S.$$

Helvin affords the only known example of a native compound of a silicate with a sulphide. It is found in the gneiss of Schwarzenberg, in Saxony, associated with garnet, quartz, flints, and calcspar: at Breitenbrunn, in Saxony; and on the Hortekalle, a mountain in the Liesthal, near Drammen, in Norway.

HEMIBROMHYDRIN. See BROMHYDRINS.

HEMIHEDRY. See CRYSTALLOGRAPHY (ii. 121, 128, 136, 140, 150, 156).

HEMILOGOUS SERIES. A name applied by Schiel (Zeitschr. Ch. Pharm. 1860, p. 44) to series of organic compounds, the terms of which differ from one another by *n*CH.

HEMIMORPHISM. Hemimorphous crystals, according to most authors, are those which are unsymmetrically terminated at the two ends of the principal axis, *e. g.* siliceous calamine (i. 714), sulphate of magnesium (ii. 150). Laurent, however (Compt. chim. 1849, p. 269), applied the same term to bodies which are similar, or to a certain extent analogous, in composition (*d'une certaine analogie dans leur composition*), and crystallise in forms (belonging to the same or to different systems) in which some of the dihedral angles are nearly equal, while the rest are very unequal.

HEMIMORPHITE. Syn. with SILICEOUS CALAMINE (i. 714).

HEMIPINIC ACID. $C^{10}H^{10}O^6$. (Wöhler [1844], Ann. Ch. Pharm. i. 17.—Blyth, *ibid.* l. 36 and 43.—Anderson, *ibid.* lxxxvi. 194.—Matthiessen and Foster, Proc. Roy. Soc. xi. 58; further, Phil. Trans. 1863; Chem. Soc. J. xv. 346.)—This acid is produced: 1. By the oxidation of opianic acid: $C^{10}H^{10}O^5 + O = C^{10}H^{10}O^6$, which may be effected by the action of peroxide of lead and sulphuric acid (Wöhler), or of aqueous dichloride of platinum (Blyth).—2. By the oxidation of narcotine with dilute nitric acid (Anderson), or with peroxide of lead and sulphuric acid, or per-

Digitized by Google

oxide of manganese and hydrochloric acid (Wöhler), or with excess of aqu dichloride of platinum (Blyth). In these reactions, the narcotine is first conve into opianic acid, which then suffers further decomposition.—3. Together with mec by the decomposition of opianic acid under the influence of caustic potash (Matthies and Foster):

$$\underset{\text{Opianic acid.}}{2C^{10}H^{10}O^5} = \underset{\text{Meconin.}}{C^{10}H^{10}O^4} + \underset{\text{Hemipinic acid.}}{C^{10}H^{10}O^6}$$

Preparation.—1. Opianic acid is heated to the boiling point with water and oxide of lead; dilute sulphuric acid is added drop by drop till carbonic acid begi escape; the liquid is left to cool partially; sulphuric acid is then added by drop all the lead is precipitated, and the filtrate is evaporated to the crystallising p The first crystals are sometimes mixed with unaltered opianic acid, but are e purified from it by their much greater solubility in water (Wöhler).—2. The mot liquor resulting from the action of dilute nitric acid upon narcotine (*q. v.*), after separation of meconin, cotarnine and opianic acid, contains hemipinic acid, which be obtained by precipitating this mother-liquor with acetate of lead, and decompo the precipitate with sulphydric acid. (Anderson.)

3. Opianic acid is mixed with a large excess of potash-ley; the liquid is evapor nearly to dryness; and the resulting alkaline mass, consisting of meconin and hemipi of potassium, is dissolved in a moderate quantity of warm water, and mixed with e of hydrochloric acid, whereby the meconin is separated as an oil, carrying down it the greater part of the hemipinic acid. The acidified liquid, when quite col poured off from the solid cake of meconin and hemipinic acid formed at the bot and evaporated to a small bulk, so as to separate the greater part of the chlorid potassium; this salt is washed with alcohol; the alcoholic washings are mixed the concentrated mother-liquor; and the fresh quantity of chloride of potassium precipitated is removed by filtration or decantation. The clear liquid is porated nearly to dryness over the water-bath; the residue thus obtaine again treated with alcohol to separate the last portions of chloride of po sium; and the alcoholic solution is filtered and evaporated. On dissolving product of these operations, together with the original precipitate of meconin hemipinic acid, in boiling water, and rendering the solution slightly alkaline ammonia, nearly all the meconin crystallises out as the solution cools, while hemipi of ammonium remains in solution, together with a small quantity of meconin. complete purification, the solution of the ammonium-salt is precipitated by acetat lead, and the hemipinate of lead, after thorough washing, is decomposed under w by sulphydric acid (Matthiessen and Foster). This mode of preparation is ferable to the oxidation process; because in the latter it is difficult to arrest the ac at the right point, so that there is always a risk, either of leaving opianic acid undec posed, or of losing a portion of the hemipinic acid by further oxidation. (See bel

Properties.—Hemipinic acid crystallises in colourless oblique rhombic pri (Wöhler), or large flat rhombohedrons (Blyth). It has a slightly acid astring taste, and a strong acid reaction. It dissolves with difficulty in cold *water*, more ea in *alcohol* and in *ether*. The crystals effloresce in the air, and give off 13·73 per c (= 2 at.) water at 100° C. At 180° it melts, and solidifies to a crystalline mass cooling. Heated between two watch-glasses, it sublimes in shining laminæ benzoic acid.

Decompositions.—Hemipinic acid burns with a bright flame. Heated with *perox of lead* and *sulphuric acid*, it appears to be completely resolved into water and carbo anhydride (Wöhler); distilled with excess of concentrated *hydriodic acid*, it is c pletely resolved into carbonic anhydride, iodide of methyl, and hypogallic a (Matthiessen and Foster):

$$\underset{\text{Hemipinic acid.}}{C^{10}H^{10}O^6} + 2HI = \underset{\text{Hypogallic acid.}}{C^7H^6O^4} + \underset{\text{Iodide of methyl.}}{2CH^3I} + CO^2$$

Heated with two or three times its weight of strong *hydrochloric acid*—either i sealed tube to about 110°, or in an open vessel connected with a condenser, in s a manner that the condensed vapour flows back into the mixture, and with an ap ratus for evolving hydrochloric acid gas, so that the liquid can be kept constan saturated with acid, it is resolved into carbonic anhydride, chloride of methyl, and acid having the composition $C^8H^8O^4$, homologous, therefore, with hypogallic acid:

$$C^{10}H^{10}O^6 + HCl = CO^2 + CH^3Cl + C^8H^8O^4.$$

This acid (not yet named) crystallises in long transparent prisms, nearly insoluble in c water, not much more soluble in boiling water, more easily soluble in alcohol and eth When heated, it begins to sublime without decomposition at about 200° C., and be a temperature of more than 245° without alteration, but at a still higher temperatu

Digitized by Google

it melts, and solidifies to a crystalline mass on cooling. It dissolves in strong sulphuric acid, and crystallises unchanged from a warm saturated solution; a cold solution is not precipitated by water. It gives no coloration with ferric chloride, with nitrate of silver it forms a white precipitate, which blackens on boiling. (Matthiessen and Foster.)

When the mother-liquor from which this acid has crystallised is subjected to the prolonged action of hydrochloric acid, hypogallic acid appears to be formed. (Matthiessen and Foster.)

Hemipinates.—Hemipinic acid is dibasic, its normal salts being represented by the formula $C^{10}H^2M^2O^6$. It is distinguished from opianic acid by forming insoluble salts with *lead*, *silver*, and *iron*. The *ammonium-salt* forms crystals permanent in the air.

The *neutral potassium-salt* is very soluble and difficult to crystallise.

The *acid potassium-salt*, $C^{10}H^2KO^6.\frac{1}{2}H^2O$, forms large hexagonal tables, easily soluble in water and alcohol, insoluble in ether. It gives off its water at 100°.

Barium-salt.—When a solution of hemipinic acid is neutralised with baryta-water, or when solutions of hemipinate of ammonium and chloride of barium are mixed together, the liquid remains clear for a long while if left to itself; but on boiling it for a short time, small, shining crystalline plates of hemipinate of barium are precipitated, and soon fill the liquid, provided the solutions used were not too dilute. The liquid on cooling redissolves this precipitate, and becomes almost or quite clear; but after standing for a few hours, or for a day or two, it again deposits hemipinate of barium, but this time in feathery tufts of very small silky needles; if the liquid be now again heated, these feathery crystals redissolve, and the crystalline plates again make their appearance. This reaction affords the means of recognising hemipinic acid, even when present in small quantity only. (Matthiessen and Foster.)

Ferric hemipinate is a precipitate of a fine orange-yellow colour (Blyth). The *lead-salt* is a white precipitate insoluble in water, but soluble in aqueous acetate of lead, whence it separates in transparent nodules (Wöhler). The *silver-salt*, $C^{10}H^2Ag^2O^6$, is a white precipitate insoluble in water.

Ethyl-hemipinic acid, $C^{10}H^2(C^2H^5)O^6.\frac{1}{2}H^2O$, is obtained by passing hydrochloric acid gas into a solution of hemipinic acid in absolute alcohol. It crystallises in bulky needles, which give off their water (9·6 per cent.) at 100°. It has a strong acid reaction, is very slightly soluble in cold water, rather more in boiling water. The aqueous solution precipitates ferric salts, but not lead- or silver-salts. The ethyl-hemipinates are difficult to purify. The *barium-salt* forms needles grouped in tufts. (Anderson.)

HEPATIN. Syn. with GLYCOGEN (ii. 906).

HEPATITE. A variety of heavy spar containing bituminous matter, and distinguished by the hepatic odour which it emits when rubbed or struck.

HEPTYL. C^7H^{15}. *Œnanthyl.*—The radicle, not yet isolated, of heptylic or œnanthylic alcohol and its derivatives.

HEPTYL, ACETATE OF. $C^9H^{18}O^2 = \left.\begin{matrix}C^2H^3O\\C^7H^{15}\end{matrix}\right\}O$. (Bouis and Carlet, Compt. rend. lv. 140; Ann. Ch. Pharm. cxxiv. 353.—Schorlemmer, Chem. Soc. J. xvi. 217).—This compound is obtained:—1. By heating œnanthol (heptylic aldehyde, $C^7H^{14}O$) with zinc and glacial acetic acid. The nascent hydrogen thereby liberated unites with the œnanthol, forming heptylic alcohol; and this, with the excess of acetic acid forms acetate of heptyl. On washing the product with water, and agitating it with acid sulphite of sodium, to remove undecomposed œnanthol, the acetate of heptyl is obtained as an oil floating on the surface (Bouis and Carlet).—2. By decomposing chloride of heptyl with acetate of potassium. The two substances, mixed with glacial acetic acid, are heated in sealed tubes to 150°—160° C., for twelve hours. The products of the reaction are chloride of potassium, acetate of heptyl, and heptylene. On diluting the contents of the tubes with water, drying the light oily liquid which separates with chloride of calcium, and subjecting it to fractional distillation, the heptylene, which boils at 95°, is easily separated from the acetate of heptyl, the boiling point of which is much higher (Schorlemmer). Alcohol may be used in the preparation instead of glacial acetic acid, but it is less convenient, as the last portions of the chloride are then very slow to decompose, requiring a heat of 200° continued for several days. (Schorlemmer.)

Acetate of heptyl is a colourless oily liquid, lighter than water, having an agreeable fruity odour, and boiling at 180° (Bouis and Carlet), between 179° and 181° (Schorlemmer), which is about 10° higher than it should be according to Kopp's law (p. 90). It contains, according to the mean of Schorlemmer's analyses, 68·18 per cent. carbon, and 11·54 hydrogen, the formula requiring 68·35 carbon and 11·39

Digitized by Google

hydrogen.—By distillation with potash-ley, it yields acetate of potassium and heptylic alcohol.

HEPTYL, BROMIDE OF. This compound is slowly produced, with evolution of hydrobromic acid, when bromine is added to hydride of heptyl, and the mixture is either exposed to sunshine or heated in sealed tubes to 100°; the action may be quickened by adding a little iodine. On distilling the product, a large quantity of undecomposed hydride passes over first, and, as soon as the temperature rises to 110°, the residue begins to decompose and blacken. (Schorlemmer, *loc. cit.*)

HEPTYL, CHLORIDE OF. $C^7H^{15}Cl$. (Petersen, Ann. Ch. Pharm. cxviii. 74. —Schorlemmer, Chem. Soc. J. xv. 423; xvi. 217, 426).—Obtained:—1. By the action of pentachloride of phosphorus on heptylic alcohol, and purified by washing and distillation in the usual way (Petersen).—2. By the action of chlorine, or better of chloride of iodine, on hydride of heptyl. Chlorine gas is passed, not in excess, into a solution of iodine in hydride of heptyl; the unattacked portion of the hydride is then distilled off, and the chloride of heptyl is separated by fractional distillation from the portion boiling between 140° and 160° (Schorlemmer).—3. In like manner, from ethyl-amyl ($C^2H^5.C^5H^{11}$), which is isomeric with hydride of heptyl. The product yields, by fractional distillation, two liquids of constant boiling point, *viz.*, chloride of heptyl, and monochlorinated chloride of heptyl, which are easily separated by distillation, as their boiling points differ by 40°. (Schorlemmer, Chem. Soc. J. xvi. 426.)

Chloride of heptyl is a colourless liquid, having an agreeable fruity odour, and burning with a smoky green-bordered flame. Specific gravity 0·891 at 19°. (Schorlemmer); 0·9983 at 55° (Petersen). Boiling point of the chloride obtained from castor-oil alcohol = 175° (Petersen); of that obtained from hydride of heptyl or from ethyl-amyl = 150° (Schorlemmer). This difference seems to point to the existence of two isomeric modifications of chloride of heptyl. Neither boiling point agrees very well with that calculated according to Kopp's law (p. 91): for the average difference for homologous chlorides of the alcohol-radicles, C^nH^{2n+1}, is about 30°, chloride of ethyl boiling at 11°, and chloride of amyl at 101°: hence chloride of heptyl should boil at about 161°.

Chloride of heptyl contains, according to Petersen's analyses, from 61·68 to 62·25 per cent. carbon, 11·01 to 11·28 hydrogen, and 26·46 chlorine, the formula requiring 62·45 C, 11·16 H, and 26·36 Cl. It is insoluble in *water*, but dissolves easily in *alcohol* and *ether*. Heated in a sealed tube with *acetate of potassium* and alcohol or glacial acetic acid, it yields acetate of heptyl (p. 141); and when heated in like manner with alcoholic *sulphydrate of potassium*, it yields sulphydrate of heptyl. It is scarcely acted upon by strong *potash-ley*, even when heated with it in sealed tubes to 180° for several days, only a small quantity of heptylene being formed, and not a trace of heptylic alcohol. (Schorlemmer.)

Monochlorinated Chloride of Heptyl, $C^7H^{14}Cl.Cl$, isomeric, if not identical, with chloride of heptylene, $C^7H^{14}Cl^2$, is obtained, together with chloride of heptyl, by the action of chloride of iodine on ethyl-amyl (see above). It boils at 190°, and gives by analysis 41·85 per cent. chlorine, the formula requiring 42·01. (Schorlemmer.)

HEPTYL, HYDRATE OF. $C^7H^{16}O = \left.\begin{matrix}C^7H^{15}\\H\end{matrix}\right\}O$. *Heptylic* or *Oenanthylic alcohol*.—This alcohol occurs, together with others, in the fusel-oil from the brandy distilled from marc of grapes (*Weintreber-fuselöl*). The portion of this liquid boiling above 133° C. contains several alcohols of the series $C^nH^{2n+2}O$, higher than amylic alcohol; and by subjecting it to repeated fractional distillation, a portion may be obtained which boils between 155° and 160°, and exhibits the composition and reactions of heptylic alcohol. (Faget, Bull. Soc. Chim. de Paris, 1862, p. 59; Ann. Ch. Pharm. cxxiv. 355.)

Heptylic alcohol is likewise obtained:—1. By the action of nascent hydrogen on œnanthol, $C^7H^{14}O$ (Bouis and Carlet). The œnanthol is treated with zinc and glacial acetic acid, as already described (p. 143), and the resulting acetate of heptyl, distilled with potash, yields the alcohol.—2. From hydride of heptyl, that compound being first converted into chloride, the chloride into acetate, and the acetate into the alcohol by distillation with potash. (Schorlemmer.)

3. By distilling ricinoleate of potassium or sodium with excess of the caustic alkali (i. 98). When castor-oil is saponified with potash and the resulting soap (ricinoleate of potassium) is distilled with excess of solid potash, hydrogen is evolved, and an oily liquid passes over, containing an alcohol, or perhaps two, homologous with ethylic alcohol, together with an aldehyde or an acetone, while sebate of potassium remains in the retort. Bouis, who first observed this reaction, originally regarded the volatile oily product as octylic or caprylic alcohol (Compt. rend. xxxiii. 144; Ann. Ch. Pharm. lxxx. 304). Soon afterwards (Institut, 1851, p. 258; Ann. Ch. Pharm. lxxx. 306) he pronounced it to be heptylic alcohol; but ultimately (Compt.

Digitized by Google

rend. xxxviii. 935; xli. 603; Ann. Ch. Pharm. xcii. 395; xcvii. 34; in detail, Ann. Ch. Phys. [3] xliv. 77; xlviii. 99), after having succeeded in purifying the alcohol more completely than before, he returned to his first opinion, which was corroborated by the analysis of several derivatives of the alcohol by himself, and also by Moschnin (Ann. Ch. Pharm. lxxxvii. 111), Squire (Chem. Soc. Qu. J. vii. 108), and Cahours (Ann. Ch. Pharm. xcii. 399).—On the other hand, Railton (Chem. Soc. Qu. J. vi. 205), from a determination of the vapour-density, and Wills (*ibid.* 307), from an analysis of the alcohol, and from the examination of some of its compound ethers, concluded that it is heptylic alcohol. Somewhat later, Limpricht (Ann. Ch. Pharm. xciii. 242) showed that the oily distillate obtained as above contains a considerable quantity of a liquid which forms a crystalline compound with acid sulphite of sodium; and by distilling this compound with excess of caustic alkali, he obtained a liquid having the composition of octylic or caprylic aldehyde, $C^8H^{16}O$, which he accordingly regarded as the chief product of the distillation of ricinoleic acid with excess of potash. According to Städeler, however (J. pr. Chem. lxii. 241; Jahresber. 1857, p. 361), the compound $C^8H^{16}O$ is not caprylic aldehyde, but the isomeric compound, methyl-œnanthyl, $CH^3.C^7H^{13}O$, belonging to the class of acetones (i. 31), and its formation takes place simultaneously with that of heptylic alcohol, in the manner shown by the equations:

$$\underset{\text{Ricinoleic acid.}}{C^{18}H^{34}O^3} + 2KHO = \underset{\text{Methyl-œnanthyl.}}{CH^3.C^7H^{13}O} + \underset{\text{Sebate of potassium.}}{C^{10}H^{16}K^2O^4} + 2H^2$$

$$\underset{\text{Ricinoleic acid.}}{C^{18}H^{34}O^3} + 2KHO = \underset{\text{Heptylic alcohol.}}{C^7H^{16}O} + \underset{\text{Sebate of potassium.}}{C^{10}H^{16}K^2O^4} + \underset{\text{Marsh gas.}}{CH^4}$$

The evolution of marsh gas, which the latter equation supposes, has not, however, been observed: the gas evolved appears to be in all cases pure hydrogen. Städeler's analysis of the alcohol agrees very closely with the formula of heptylic alcohol. Similar results have been obtained by Petersen (Ann. Ch. Pharm. cxvii. 69), who analysed the alcohol after carefully freeing it from methyl-œnanthyl, and also some of its derivatives, all of which gave results agreeing with the 7-carbon formulæ. On the other hand, Dachauer (Ann. Ch. Pharm. cvi. 269), from his analyses of the carefully-purified alcohol and several of its derivatives, has come to the conclusion that the volatile products of the reaction are methyl-œnanthyl and octylic alcohol, the formation of the latter differing from that of the former, only by the evolution of 2 at. hydrogen instead of four:

$$\underset{\text{Ricinoleic acid.}}{C^{18}H^{34}O^3} + 2KHO = \underset{\text{Octylic alcohol.}}{C^8H^{18}O} + \underset{\text{Sebate of potassium.}}{C^{10}H^{16}K^2O^4} + H^2.$$

From these various statements it appears probable that both heptylic and octylic alcohol may be produced in this reaction. It must be observed, however, that the percentage of carbon in the two alcohols differs by only 1·4 per cent., and that the percentage of carbon in heptylic alcohol (72·4) might easily be raised to that of octylic alcohol (73·8) by the admixture of a certain quantity of methyl-œnanthyl, which contains more carbon than either of them (75·0 per cent.), and is very difficult to separate from the alcohol. It is possible, therefore, that the alcohol obtained may be in all cases the heptylic, but that some chemists who have analysed it have not succeeded in completely removing the methyl-œnanthyl. On the other hand, assuming the received formula of ricinoleic acid to be correct (and it is confirmed by Petersen's analyses, *loc. cit.*), the formation of the 7-carbon alcohol, together with sebacic acid, does not account for the whole of the carbon, unless we suppose marsh gas to be evolved, which has not been observed by any one. The subject, therefore, requires further investigation.

Preparation of Heptylic alcohol from Castor-oil.—The oil is saponified with caustic soda, and the ricinoleate of sodium, separated in the usual way by common salt, is distilled by small portions with excess of caustic soda, as long as the distillate continues to pass over colourless. The portion collected between 170° and 180° is rectified over solid potash, washed, and shaken up with a concentrated solution of acid sulphite of sodium; and the thick pulp which forms after a while is separated from the mother-liquor by pressing it and transferring it to a moist filter. The whole mass is then repeatedly agitated with ether, in which the alcohol is soluble, but the compound of the acetone with the alkaline sulphite is insoluble. The ethereal solution is then filtered off; the ether removed by distillation, the residual oil again mixed with strong solution of acid sulphite of sodium, and set aside for several days; the watery liquid again separated from the mass, which has now become gelatinous; this mass is exhausted with ether; and the oil obtained from this ethereal solution is again treated several times with sulphite of sodium, being ultimately left in contact with it for several weeks, or as long

Digitized by Google

as any small quantity of gelatinous precipitate continues to separate. The oil finally obtained after evaporating the ether is rectified over a small quantity of hydrate of potassium, then washed with water and dried. The product thus obtained is heptylic alcohol. (Petersen.)

Properties.—Heptylic alcohol is a colourless oily liquid, insoluble in water, soluble in common alcohol and in ether. Specific gravity 0·819 at 23° (Städeler). Vapour-density 4·34 (Petersen), 4·16 (Faget), 4·019, by determination in an atmosphere of hydrogen (Railton): by calculation (2 vol.) = 4·04. Boiling point 179° (Wills), between 177 and 177·5° (Städeler), 178·5° (Petersen), 165° (Bouis and Carlet), between 155° and 160° (Faget). These differences, as with the chloride, indicate the existence of two modifications of the alcohol. The calculated boiling point, according to Kopp's law, is 173° (p. 90), so that the heptylic alcohol obtained from castor-oil appears to be the normal compound, whereas the alcohol obtained from brandy fusel-oil, and that produced from œnanthol, appear to correspond with Wanklyn and Erlenmeyer's β-hexylic alcohol, inasmuch as the latter boils at 134°, and 137 + 19 = 156.

The following table exhibits the composition of heptylic alcohol as determined by calculation and by analysis:

	Calculation.		Wills.	Städeler, *mean.*	Petersen.	Faget.	Schorlemmer, *mean.*
C^7	84	72·4	72·79	72·33	72·21	72·43	72·25
H^{16}	16	13·8	13·67	13·55	13·99	13·84	14·24
O	16	13·8	13·54	14·12	13·80	13·73	13·51
$C^7H^{16}O$	116	100·0	100·00	100·00	100·00	100·00	100·00

Faget's alcohol was obtained from brandy fusel-oil (p. 144); Schorlemmer's was prepared from hydride of heptyl obtained from Boghead naphtha; the other three from castor-oil. Petersen observes that the purification of the alcohol did not always succeed so completely as in the sample whose analysis is above given; in one specimen he found 72·95 per cent. carbon and 13·37 hydrogen. Bouis, Moschnin, and Dachauer, as already observed, have obtained, by their analyses of the castor-oil alcohol, results agreeing more nearly with the formula $C^8H^{18}O$, viz. Bouis, 73·5 C, 13·9 H; Moschnin, 73·6 C, 13·8 H; Dachauer, 73·8 C, 13·9 H (calc. 73·8 C, 13·8 H). See OCTYLIC ALCOHOL.

Decompositions.—1. Heptylic alcohol distilled with *chloride of zinc*, yields heptylene, C^7H^{14} (Bouis and Carlet).—2. Heated with *potash-lime*, it gives off hydrogen, and is converted into œnanthylic acid, $C^7H^{14}O^2$ (Faget).—3. With *pentachloride of phosphorus*, it yields chloride of heptyl (Petersen), and with *iodine* and *phosphorus*, iodide of heptyl (Schorlemmer).—4. With *sulphuric acid*, it forms heptyl-sulphuric acid, $C^7H^{16}SO^4$ (Petersen).

HEPTYL, HYDRIDE OF. $C^7H^{16} = C^7H^{15}.H$.—This compound occurs, together with several of its homologues, in rectified American petroleum (Pelouze and Cahours, Compt. rend. lvi. 505; Ann. Ch. Pharm. cxxvii. 196.—Schorlemmer, Proc. Lit. Phil. Soc. Manchester, March 13, 1863; Chem. Soc. J. xvi. 216) and in the light oil obtained from the tar of cannel-coal (Schorlemmer, Chem. Soc. J. xv. 423): it is also produced, together with some of its homologues and other hydrocarbons, by distilling amylic alcohol with chloride of zinc. (A. Wurtz, Compt. rend. lvi. 1164, 1246; Ann. Ch. Pharm. cxxviii. 225.)

1. Rectified American petroleum may be separated by fractional distillation into the hydrides of twelve alcohol-radicles, from hydride of tetryl, C^4H^{10}, boiling at a few degrees above 0°, to hydride of pentadecatyl, $C^{15}H^{32}$, boiling between 255° and 260°, besides others of still higher boiling point (see HYDRIDES). When the liquid which remains after the separation of the hydrides of amyl, boiling at 30°, and hexyl, at 68°, is submitted to further rectification, the temperature remains constant for some time between 90° and 96°; and if the portion which passes over between these temperatures be collected apart and again carefully rectified, the quantity of material being somewhat considerable, a product may be isolated which, after purification by shaking it up with very concentrated sulphuric acid, washing with dilute carbonate of sodium, and dehydration with chloride of calcium, boils between 92° and 94°: this is hydride of heptyl. (Pelouze and Cahours.)

2. The mixture of oils obtained by distilling cannel-coal at as low a temperature as possible, is left in contact for several days with an equal volume of sulphuric acid, and frequently shaken; the oil is then poured off, washed with water, and distilled; and the distillate, consisting of benzene and benzylene (toluene), together with the hydrides of the alcohol-radicles, is repeatedly shaken with strong nitric acid, to convert the benzene and benzylene into nitro-compounds, until, on adding water to the liquid, no further separation of these compounds occurs. The portion unacted upon by the nitric acid is then washed with water, dried over potash, and repeatedly rectified over sodium. The liquid thus obtained yields by fractional distillation, hydride of amyl, C^5H^{12}, boiling at

Digitized by Google

39°—40° C., hydride of hexyl at 68°—70° hydride of heptyl at 98°—99°, and hydride of octyl at 119°—120°. (Schorlemmer.)

3. The distillate obtained by heating amylic alcohol with chloride of zinc consists of amylene and compounds polymeric with it, together with hydride of amyl, and smaller quantities of the hydrides of hexyl, heptyl, &c., up to $C^{10}H^{22}$. Heptylene and hydride of heptyl are contained in the portion of the distillate boiling between 85° and 95°, and may be separated by converting the heptylene into a bromide and distilling, the hydride of heptyl then passing over first. (Wurtz.)

Hydride of heptyl is a thin mobile liquid, having a faint but pleasant odour, and burning with a slightly smoky flame. Specific gravity 0·7122 at 16°; 0·709 at 17·5° (Schorlemmer). Boils at 98°—99° (Schorlemmer), at 92°—94° (Pelouze and Cahours). Vapour-density by experiment, 3·49—3·59 (Schorlemmer), 3·616 (Pelouze and Cahours); by calculation (2 vol.) = 3·46. It gives by analysis 83·93 and 84·0 per cent. carbon, 16·13 and 16·1 hydrogen, the formula requiring 84 C and 16 H (Schorlemmer). By *chlorine*, and more quickly by *chloride of iodine*, it is converted into chloride of heptyl. Chlorine passed into hydride of heptyl forms, besides chloride of heptyl, small quantities of some other chlorine-compounds, which, when distilled with sodium, yield a liquid boiling at 95°—100°, and having the odour and composition of heptylene (Schorlemmer, Chem. Soc. J. xv. 424). With *bromine*, hydride of heptyl appears to yield bromide of heptyl (p. 144).

HEPTYL, IODIDE OF. $C^7H^{15}I$.—Obtained by the action of iodine and phosphorus on heptylic alcohol (Schorlemmer, Chem. Soc. J. xvi. 219.—Petersen, Ann. Ch. Pharm. cxviii. 74). It is a colourless liquid, heavier than water, quickly turning brown in contact with the air, boiling at 190° (Schorlemmer), 192° (Petersen). Composition by analysis, 37·19 per cent. C, 6·73 H, and 56·18 I; by calculation, 37·17 C, 6·64 H, and 56·19 I. It is instantly decomposed by alcoholic nitrate of silver, the whole of the iodine being separated as iodide of silver. (Schorlemmer.)

HEPTYL, SULPHYDRATE OF. $C^7H^{15}S = C^7H^{15}.H.S.$—Obtained by heating chloride of heptyl with alcoholic sulphydrate of potassium in a sealed tube. Colourless liquid, boiling between 155° and 158°, having a mercaptan-like, as well as aromatic, odour, and exhibiting all the characteristic reactions of the mercaptans. (Schorlemmer.)

HEPTYLAMINE. $C^7H^{17}N = N.H^2.C^7H^{15}$.—Obtained: 1. By saturating iodide of heptyl with ammonia, heating the solution in the oil-bath, and removing the iodine with oxide of silver (Petersen, *loc. cit.*).—2. By heating chloride of heptyl with ammonia in sealed tubes to 120° for several days. The chlorides of the different heptyl-ammoniums are then formed, but chiefly chloride of heptyl-ammonium, $C^7H^{15}Cl$. This salt dissolves easily in water and alcohol, and crystallises in small scales. When distilled with caustic potash, it yields heptylamine, as a light oily liquid, having an ammoniacal aromatic odour, a burning taste, and boiling at 145°—147°. It is moderately soluble in water, and separates out again on addition of caustic potash. (Schorlemmer, Chem. Soc. J. xvi. 221.)

The *platinum-salt*, $2C^7H^{15}NCl.PtCl^4$, is slightly soluble in cold water, freely soluble in hot water, also in alcohol and ether, crystallising from these solutions in small yellow scales. Gives by analysis 30·7 per cent. platinum (Schorlemmer); 30·9 (Petersen); calc. 30·79.

HEPTYLAMYLIC ETHER. $C^{12}H^{26}O = C^7H^{15}.C^5H^{11}.O$. *Amylœnanthylic ether.*—Produced by the action of heptylate of sodium on an equivalent quantity of iodide of amyl, and obtained, though with some difficulty, by submitting the product to fractional distillation, as a colourless mobile liquid, boiling between 220° and 221°. Specific gravity = 0·808 at 20°. Vapour-density: obs. = 6·57; calc. (2 vols.) = 6·45. Analysis 77·0 per cent. C, and 13·8 H. Calculated composition, 77·4 C, 14·0 H, and 8·6 O. (Wills, Chem. Soc. J. vi. 316.)

HEPTYLENE. C^7H^{14}. *Œnanthylene.*—This hydrocarbon, homologous and polymeric with ethylene, is contained, together with others of the series C^nH^{2n}, and hydrocarbons belonging to the series C^nH^{2n+2} and C^nH^{2n-6}, in the light oil obtained by the distillation of Boghead coal. By treating this oil with bromine in presence of water, the hydrocarbons C^nH^{2n} are converted into heavy oily bromides, while the other hydrocarbons remain unaltered and may be distilled off. The remaining liquid separates, on standing, into three layers, the upper consisting of water with a little hydrobromic acid, the middle of the organic bromides, and the lowest of aqueous hydrobromic acid. The middle layer separated and distilled with alcoholic potash and with sodium, yields the hydrocarbons C^nH^{2n}. The brominated oils obtained from the fractions of the original coal-oil which boiled between 71° and 77° and between 82° and 88°, yielded respectively hexylene boiling at 71° and heptylene boiling at 99° (Greville Williams, Phil. Trans. 1857 [3] 737; Ann. Ch. Pharm. cviii. 384). Heptylene is likewise obtained:—1. By decomposing chloride of heptylene with sodium at a gentle heat.

Digitized by Google

The sodium is added by small quantities; the liquid distilled off as soon as the quantity of chloride of sodium becomes so great as to interfere with the action; and the distillate is treated with fresh sodium, the last traces of chlorine being removed by repeatedly rectifying the product over perfectly bright sodium (Limpricht, Ann. Ch. Pharm. ciii. 80). The heptylene which Schorlemmer obtained by treating with sodium the chlorinated compounds produced, in addition to chloride of heptyl, by the action of chlorine on hydride of heptyl (p. 144), probably also resulted from the decomposition of chloride of heptylene.—2. By distilling heptylic alcohol with chloride of zinc: $C^7H^{16}O - H^2O = C^7H^{14}$ (Bouis and Carlet).—3. By heating chloride of heptyl with strong aqueous potash to 180° in sealed tubes for several days (Schorlemmer, p. 144).—Bouis, in 1855, by distilling œnanthol with strong sulphuric acid, obtained a hydrocarbon agreeing in composition with the empirical formula of the olefines, CH^2, and supposed by him to be heptylene; but, as it boiled at 50°, it was probably either a lower member of the series, or a mixture.

Heptylene is a colourless mobile liquid, having a peculiar alliaceous odour; soluble in alcohol. Boils at 95° (Schorlemmer), at 99° (Gr. Williams). Specific gravity 0·718 at 18° (Williams). Vapour-density, obs. = 3·320 (Williams); calc. (2 vol.) = 3·386.

	Calculation.		Limpricht.	Schorlemmer.	
C^7	84	85·71	85·9	85·6	85·66
H^{14}	14	14·29	14·1	14·6	14·00
C^7H^{14}	98	100·00	100·0	100·2	99·66

Bromide of Heptylene. $C^7H^{14}Br^2$.—Obtained by direct combination. It is a liquid, heavier than water, which decomposes on distillation, with blackening and evolution of hydrobromic acid, but volatilises in presence of aqueous vapour, condensing as a nearly colourless liquid having the odour of bromide of ethylene. Gives by analysis 62·26 and 62·23 bromine, the formula requiring 62·01. (Schorlemmer.)

Chloride of Heptylene. $C^7H^{14}Cl^2$.—Produced by the action of pentachloride of phosphorus on œnanthol. When 1 at. œnanthol is gradually allowed to flow into 1 at. pentachloride of phosphorus contained in a tubulated retort, great heat is evolved, and a portion of the resulting oxychloride of phosphorus distils over immediately. As soon as the decomposition of the pentachloride is complete, the liquid is subjected to fractional distillation, the portion which boils above 150° being collected apart as long as it passes over colourless; in the retort there remains a small quantity of a brown thick liquid. The last distillate is washed with water to remove adhering oxychloride of phosphorus; and the oil which floats on the water is shaken up with acid sulphite of sodium, to remove undecomposed œnanthol, then dried with chloride of calcium, and rectified, the portion which boils between 180° and 200° being collected apart: on again rectifying this portion, pure chloride of heptylene passes over at 187°.

Chloride of heptylene is a transparent, colourless, mobile liquid, lighter than water, having a not unpleasant odour, like that of œnanthol. It boils at 191° (corrected). Gives by analysis 48·85 per cent. C, 8·00 H, and 42·05 Cl; the formula requiring 49·4 C, 8·2 H and 42·4 Cl.

When gently heated with *sodium*, it is decomposed with violence, yielding heptylene and chloride of sodium.—Boiled for some time with ethylate of sodium or alcoholic solution of potash, it is resolved into hydrochloric acid, chlorheptylene, $C^7H^{13}Cl$, and a hydrocarbon, probably C^7H^{12}:

$$C^7H^{14}Cl^2 - HCl = C^7H^{13}Cl; \text{ and } C^7H^{14}Cl^2 - 2HCl = C^7H^{12}$$

It is not perceptibly decomposed by acetate of silver, even when continuously boiled with it, or heated to 250° in sealed tubes. (Limpricht, Ann. Ch. Pharm. ciii. 80.)

Chlorheptylene. $C^7H^{13}Cl$.—Obtained by the action of alcoholic potash or ethylate of sodium on chloride of heptylene. A very concentrated alcoholic solution of potash is distilled upwards with chloride of heptylene for a considerable time (the decomposition of 15 grammes of the chloride takes about a week);—or chloride of heptylene and ethylate of sodium are heated together in a sealed tube to 250°. The liquid obtained by either process is diluted with water, which separates impure chlorheptylene; and this crude product is dried by means of chloride of calcium and then subjected to fractional distillation. It begins to boil at 100°, the boiling point slowly rising to 150°, where it remains constant for a while and ultimately rises to 190°. The liquid which passes over below 100° is a hydrocarbon (*see below*); that which distils at 152° is chlorheptylene, and above that temperature the product consists chiefly of undecomposed chloride of heptylene. The complete separation of these liquids can only be effected by repeated rectification.

Chlorheptylene is a liquid resembling chloride of heptylene, having a similar odour, and boiling at 155° (corrected). It gives by analysis 63·5 per cent. C, 9·7 H, and 26·8 Cl, the formula requiring 63·2 C, 9·7 H and 27·1 Cl.

Digitized by Google

Sodium remains unaltered in chlorheptylene at ordinary temperatures; but on heating the liquid, a violent action suddenly takes place, chloride of sodium being formed, together with a hydrocarbon, probably C^7H^{12}.—The same hydrocarbon appears to be produced by the action of alcoholic potash on chloride of heptylene (see above). (Limpricht, Ann. Ch. Pharm. cii. 82.)

Hydriodate of Heptylene. $C^7H^{15}I = C^7H^{14}.HI$.—Obtained by heating heptylene with hydriodic acid in sealed tubes to 100° for twelve hours. It closely resembles iodide of heptyl, but boils at about 170°, or 20° lower than the latter. It soon turns brown when exposed to the air. Precipitated by alcoholic nitrate of silver, it yielded a quantity of iodide of silver corresponding to 55·73 per cent. iodine (calc. 56·19); and the filtrate, on being mixed with water, yielded a small quantity of a fragrant liquid, which consisted wholly or in a great part of nitrate of heptylene, $C^7H^{14}.NO^3H$, as on adding an alcoholic solution of potash, and heating gently, an abundant precipitate of nitrate of potassium was formed. (Schorlemmer, Chem. Soc. J. xvi. 220.)

HEPTYL-ETHYLIC ETHER. $C^9H^{20}O = C^7H^{15}.C^2H^5.O$. *Ethyl-œnanthylic ether.* (Wills, Chem. Soc. Qu. J. vi. 312;* Petersen, Ann. Ch. Pharm. cxviii. 75).—Prepared by the mutual action of iodide of ethyl and heptylate of sodium in equivalent proportions:

$$C^7H^{15}NaO + C^2H^5I = NaI + C^7H^{15}.C^2H^5.O.$$

It is a colourless mobile liquid, having a faint odour, and burning with a bright flame insoluble in water, easily soluble in alcohol and ether. Boils at 177° (Wills). Specific gravity = 0·791 at 16°. Vapour-density, obs. = 5·095 (Wills); calc. (2 vol.) = 4·99.

	Calculation.		Wills.	Petersen.
C^9	108	75·00	75·16	74·44
H^{20}	20	13·88	14·44	14·40
O	16	11·12	10·40	11·16
$C^9H^{20}O$	144	100·00	100·00	100·00

HEPTYLIC ALDEHYDE. Syn. with Œnanthol. (*q. v.*)

HEPTYL-METHYLIC ETHER. $C^8H^{18}O = C^7H^{15}.CH^3.O$. *Methyl-œnanthylic ether.* (Wills, Chem. Soc. J. vi. 314.)—Obtained by the action of iodide of methyl on heptylate of sodium. It is a thin mobile liquid, having a strong odour, insoluble in water, easily soluble in alcohol and in ether. Boiling point between 160·5° and 161°. Specific gravity = 0·830 at 16·5°. Vapour-density (obs.) about 4·2; calc. (2 vol.) = 4·5. A specimen not quite pure gave by analysis 73·15 per cent. C, and 14·09 H, the formula requiring 73·85 C and 13·85 H.

HEPTYL-SULPHURIC ACID. $C^7H^{16}SO^4 = \left.\begin{matrix}(SO^2)''\\ C^7H^{15}\\ H\end{matrix}\right\}O^2$. (Petersen, Ann. Ch. Pharm. cxviii. 72.—Bouis and Carlet, *ibid.* cxxiv. 254.)—When 2 pts. of heptylic alcohol are cautiously mixed with 1 pt. sulphuric acid, the mixture being kept cool so as to prevent the formation of sulphurous acid, the liquid ultimately separates into two layers, the upper of which contains heptyl-sulphuric acid. On neutralising it with carbonate, and at last very carefully with hydrate of barium, and concentrating at a gentle heat, heptyl-sulphate of barium separates in small, white, flexible, and generally scaly crystals, having a pearly lustre and bitter taste, very soluble in water, and not precipitated from the aqueous solution by alcohol or ether. The solution decomposes by evaporation unless the temperature be kept very moderate. The dry salt is permanent in the air, but, according to Petersen, begins to decompose at 80°, turning first red, then black, and emitting a very strong odour. According to Bouis and Carlet, on the other hand, it may be heated to 100° without decomposition. According to the mean results of Petersen's analyses, the salt dried over oil of vitriol contains 30·97 per cent. C, 6·19 H, 25·10 Ba, and 11·73 S, agreeing nearly with the formula $2C^7H^{15}BaSO^4.H^2O$, which requires 30·83 C, 5·87 H, 25·14 Ba, 11·74 S, and 26·42 O.

HERAPATHITE. Syn. with Sulphate of Iodoquinine. (See Quinine.)

HERCYNITE. An iron spinel, $FeO.Al^2O^3 = \left.\begin{matrix}Fe''\\ (Al^2)^{vi}\end{matrix}\right\}O^4$. Specific gravity 3·91—3·95. (See Spinel.)

HERDERITE. A very rare mineral, consisting of anhydrous phosphate of aluminium, and phosphate with fluoride of calcium; not yet analysed quantitatively. The crystals are trimetric. Hardness = 5. Specific gravity = 2·985. It resembles apatite in colour and lustre, but is distinguished by its lower specific gravity. Soluble in hydrochloric acid. Melts before the blowpipe to a white bead, with slight intumescence. (Dana, ii. 410.)

* The compound obtained by Wills is described at p. 342, vol. ii. as octyl-ethylic ether; but the balance of evidence is certainly in favour of the supposition that it contains heptyl, not octyl.

Digitized by Google

HERMANNITE. See RHODONITE.

HERRERITE. A mineral from Albarradon in Mexico, said by Herrera (J. pr. Chem. viii. 514) to contain 35·58 per cent. tellurium, 12·32 oxide of nickel, and 31·86 carbonic acid. According to Genth, however (*ibid.* lxvi. 475), it is a cupriferous zinc-spar, containing 93·74 per cent. $ZnCO^3$, 3·42 $CuCO^3$, 1·50 $MnCO^3$, 1·48 $CaCO^3$, and 0·29 $MgCO^3$.

HERSCHELITE. A mineral from Aci reale and Aci Castello in Sicily, having the same general formula as lime-harmotome (p. 14), viz. $M^2O.Al^4O^3.4SiO^2 + 5H^2O$, or $M^2(al'')^8Si^4O^{12}.5H^2O$, agreeing also in general formula with gmelinite (ii. 924) excepting in the amount of water, and crystallising, like the latter, in the hexagonal system.

Analyses 1 and 2 are of the mineral from Aci reale, by Damour (Ann. Ch. Phys. [3] xiv. 97); 3, 4, from Aci Castello, by v. Waltershausen (*Vulkanische Gesteine*, p. 260):

	SiO^2	Al^2O^3	Fe^2O^3	CaO	MgO	Na^2O	K^2O	H^2O.
1.	47·39	20·90	. .	0·38	. .	8·33	4·39	17·84 = 99·23
2.	47·46	20·18	. .	0·25	. .	9·35	4·17	17·65 = 99·06
3.	45·89	18·20	1·14	4·84	0·35	5·72	3·72	17·86 = 97·72
4.	47·03	20·21	1·14	4·66	0·49	4·82	2·03	17·86 = 98·24

These analyses lead to the formulæ:

Damour. $\left.\begin{matrix}\frac{2}{3}Na^2O \\ \frac{1}{3}K^2O\end{matrix}\right\} SiO^2.(Al^2O^3.3SiO^2) + 5$ aq.

v. Waltershausen. $\left.\begin{matrix}\frac{4}{5}CaO \\ \frac{1}{5}Na^2 \\ \frac{1}{5}K^2O\end{matrix}\right\} SiO^2.(Al^2O^3.3SiO^2) + 5$ aq.

According to v. Waltershausen, herschelite does not occur at Aci reale.

HESPERIDIN. A substance discovered by Lebreton (J. Pharm. xiv. 377), and contained in many fruits of the genus *Citrus*. It is most readily prepared from unripe Seville oranges, by removing the green rind and the inner part of the fruit, treating the white spongy inner coating with water at a temperature of 25 to 30°; concentrating the liquid, neutralising it with lime-water, and evaporating to a syrup; treating the residue with alcohol of 40 per cent.; then filtering, distilling off the alcohol, and agitating the bitter granular residue with 20 times its weight of distilled vinegar. The liquid on standing deposits hesperidin in warty masses, which may be washed with water and recrystallised from boiling alcohol.

Hesperidin thus purified forms white, silky laminæ, inodorous, and having a bitter taste; sparingly soluble in cold *alcohol*, very soluble in boiling alcohol, insoluble in *ether*; dissolves in 60 pts. of boiling *water*, and separates again on cooling. The solutions are neutral to vegetable colours. It is soluble in warm concentrated *acetic acid*, insoluble in *oils*.

Hesperidin is decomposed by prolonged boiling with *water*, and then floats on the surface like melted wax. It is readily dissolved by caustic *alkalis*. Strong *sulphuric acid* dissolves it with orange-colour, gradually changing to red. Hot *nitric acid* converts it into oxalic acid and a bitter substance. The alcoholic solution is not precipitated by *acetate of lead*, but forms a brown precipitate with *ferric sulphate*.

Wiedemann has described, under the name *hesperidin*, a substance obtained from unripe oranges, differing from that above described in some respects, especially in not being soluble in alcohol.

HESSITE. Telluric silver. (See TELLURIUM.)

HESSONITE. Syn. with ESSONITE (ii. 507).

HETEPOZITE. See HETEROSITE.

HETEROCLINE or *Marceline*. A silicate of manganese occurring at St. Marcel in Piedmont, in oblique rhombic prisms of 128° 16', and containing 10·76 per cent. SiO^2, 85·87 Mn^2O^3, 3·38 Fe^2O^3, 0·61 CaO, and 0·44 K^2O = 100·30. (Evreinoff, Pogg. Ann. xlix. 204.)

HETEROMERITE. An altered form of idocrase from Slatoust in Siberia, containing, according to v. Hauer, 43·29 SiO^2; 23·17 Al^2O^3; 6·10 Fe^2O^3; 23·78 CaO, and 3·05 MgO. Colour light green.

HETEROMORPHISM. The property, sometimes observed in compounds, of crystallising, in different forms, though containing equal numbers of atoms similarly grouped. Such is the case with *sulphate of zinc*, $\left.\begin{matrix}SO^2 \\ Zn''\end{matrix}\right\} O^2 + 7H^2O$, and *ferrous sulphate*, $\left.\begin{matrix}SO^2 \\ Fe''\end{matrix}\right\} O^2 + 7H^2O$; the former crystallising in the trimetric, the latter in the monoclinic

Digitized by Google

system. The cause of this difference in the examples just cited is probably that the elements—iron and zinc—are not isomorphous.

HETEROMORPHITE. *Feather ore.*—A sulphantimonite of lead, $Sb^2S^3.2PbS$, which occurs in capillary forms resembling a cobweb; also massive. Specific gravity 5·67 to 5·9. Hardness 1 to 3. Lustre dull metallic. Colour lead-grey to steel-grey, sometimes iridescent. It is found at Wolfberg in the Eastern Hartz; also at Andreasberg and Clausthal; at Freiberg and Schemnitz; in the Anhalt at Pfaffenberg and Meiseberg; and in Tuscany, near Bottino. (Dana, ii. 76.)

HETEROSITE or *Hetepozite.* A hydrated phosphate of iron and manganese, found near Limoges, in dark brown or black masses, containing, according to Dufrénoy's analysis, 41·77 p. c. P^2O^5, 34·89 FeO, 17·57 MnO, 4·40 H^2O, and 0·22 SiO^2 (= 98·85), whence Rammelsberg (*Mineralchemie*, p. 331) deduces the formula $3(5MO.2P^2O^5)$ or $3\left[\begin{matrix}3FeO\\MnO\end{matrix}\right\}2P^2O^5] + 5$ aq.

The same name is applied to an altered triphyllin from Chanteloub, Limoges, of brownish violet colour, specific gravity 3·41, and containing 32·18 p. c. P^2O^5, 31·46 Fe^2O^3, 30·01 Mn^2O^3, and 6·35 water (= 100), whence the formula $5M^2O^3.3P^2O^5 + 5$ aq. (Rammelsberg, *loc. cit.*)

HEULANDITE. See STILBITE.

HEVENE. The least volatile part of the products of the dry distillation of caoutchouc and gutta percha. It is an oily hydrocarbon, of an amber-yellow colour, acrid taste, and specific gravity 0·921 at 21°. Boils at 315°. Mixes in all proportions with alcohol, ether, and oils, both fat and volatile. It rapidly absorbs chlorine, and acquires thereby the consistence of wax. It is partly resinised by sulphuric acid, and then converted into an oil which boils at 228°, and is not attacked by strong acids (Bouchardat, Ann. Ch. Pharm. xxvii. 30). According to Greville Williams, it is probably polymeric with isoprene and caoutchin (ii. 961).

HEXACHLORXYLIN. A product of the action of chlorine on hydrate of phenyl. (See PHENYL.)

HEXACROLEIC ACID. $C^{18}H^{24}O^4$.—An acid polymeric with acrolein, and produced by dropping that liquid into an alcoholic solution of potash. The solution becomes heated to the boiling point; and on addition of an acid, yields hexacroleic acid as a yellow, amorphous, feebly acid substance, soluble in alkalis, alcohol and ether; insoluble in water, easily fusible, but not volatile without decomposition. Most of its salts are insoluble in water. (Claus, Ann. Ch. Pharm. suppl. ii. 117.)

HEXAMETAPHOSPHORIC ACID. See PHOSPHORIC ACID.

HEXAMETHYLENAMINE. $C^6H^{12}N^4 = N\left\{\begin{matrix}N(CH^2)^2\\N(CH^2)^2\\N(CH^2)^2\end{matrix}\right.$.—A volatile crystalline base produced by the action of ammonia on dioxymethylene (Butlerow, Ann. Ch. Pharm. cxv. 322). See METHYLENAMINES.

HEXMETHYLENIC ALCOHOL. See ETHYLENE, HYDRATES OF (ii. 576).

HEXMETHYL-ETHYLENE-DIPHOSPHONIUM. See PHOSPHORUS-BASES.

HEXYL. *Caproyl.* $C^{12}H^{26} = \begin{matrix}C^6H^{13}\\C^6H^{13}\end{matrix}$.—The sixth alcohol-radicle of the series C^nH^{2n+1}. It is produced by the electrolysis of œnanthylic acid:

$$C^7H^{14}O^2 = C^6H^{13} + H + CO^2.$$

To prepare it, a solution of œnanthylate of potassium is decomposed by a voltaic current, and the oil which separates is dried over chloride of calcium, and then distilled with alcoholic potash, which retains œnanthylic acid, while the hexyl passes over with the vapours of alcohol, and may be purified by washing with water and rectification (Brazier and Gossleth, Chem. Soc. J. iii. 210). Wurtz (Ann. Ch. Phys. [3] xliv. 275), by electrolysing a mixture of 100 pts. œnanthylic and 120 pts. valeric acid, neutralising with potash and cooling to 0°, obtained an oil which, after desiccation by chloride of calcium, yielded by fractional distillation, tetryl (C^4H^9), boiling between 100° and 140°, tetryl-hexyl ($C^4H^9.C^6H^{13}$), between 140° and 180°, and a portion boiling between 180° and 220°, consisting chiefly of hexyl.

Hexyl is a colourless oily liquid, of specific gravity 0·7574 at 0°. It boils at 202°, yielding a vapour whose density is 5·983 (Wurtz); calc. (2 vol.) = 5·8979. It is insoluble in water, but soluble in alcohol and ether.

It is not attacked by sulphuric acid, and may be distilled without alteration with moderately concentrated nitric acid; but by repeated distillation with a mixture of sulphuric and nitric acids, it is converted into an acid, probably caproic acid. It is

Digitized by Google

scarcely attacked by bromine, even in sunshine. Chlorine attacks it strongly, even in diffused daylight; hydrochloric acid being evolved, and a viscid substance formed, which gives off hydrochloric acid when distilled, and leaves a residue of charcoal. (Brazier and Gossleth.)

The compounds of hexyl were hardly known before the year 1861, the alcohol having been barely identified by Faget, in fusel-oil, in 1854 (Compt. rend. xxxvii. 730). At present, the known sources of hexyl-compounds are: (1) fusel-oil, containing the alcohol; (2) mannite and melampyrin, which, when reduced with hydriodic acid, give iodide of hexyl; and (3) petroleum and coal-tar oil, which contain hydride of hexyl. Whether the hexyl-compounds obtained from (1) and (3) are identical, is still an open question; but, without doubt, those derived from (2) are essentially different from the hexyl-compounds either of fusel-oil or of petroleum. The hexyl-compounds of fusel-oil and of petroleum have been distinguished by the prefix *Alpha*, those of mannite or melampyrin by *Beta*. The former compounds, so far as they have been yet examined, present the very closest analogies to those of the ethyl series; the latter depart in many ways from this standard: thus, they show a great tendency to evolve their olefine during reactions; and their alcohol has too low a boiling point, and when oxidised with dilute chromic acid, does not yield caproic acid, but breaks up into carbonic acid, water, butyric and acetic acids.

The hexyl-compounds derive peculiar interest from their having the same carbon-condensation as the sugars, and from their standing in close relation thereto, as the reaction of hydriodic acid with mannite proves, mannite being, as has long been known, a product of the reduction of glucose (ii. 864).

Berthelot has already remarked upon the peculiar readiness to react shown by tritylene. It is not unworthy of remark, that hexylene, which is paratritylene, likewise displays extraordinary energy.

Acetates of Hexyl.—*α Hexyl-acetate* is prepared by the action of α iodide of hexyl upon acetate of silver. It is a colourless liquid, lighter than water, and boiling at about 145° C. By the action of caustic potash, it has been transformed into an alcohol, boiling at about 150°. (Cahours and Pelouze, Compt. rend. liv. 1245.)

β Hexyl-acetate is prepared by distilling β hexyl-sulphuric acid with a great excess of glacial acetic acid:—

$$\left.\begin{matrix}\beta\,C^6H^{13}\\H\end{matrix}\right\}SO^4 + \left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O = \left.\begin{matrix}H\\H\end{matrix}\right\}SO^4 + \left.\begin{matrix}C^2H^3O\\\beta\,C^6H^{13}\end{matrix}\right\}O.$$

It is an oil lighter than water, and very insoluble in water, having a peculiar smell, unlike the usual smell of an acetate of an alcohol-radicle. Boiling point 156°. It distils without decomposition. Digestion at 100°, with an alcoholic solution of potash, transforms it into β hexylic alcohol. Unlike β $C^6H^{13}I$, it yields no hexylene on digestion with alcoholic solution of potash. Sp. gr. at 0° = ·8778 : at 50° = ·8310; therefore expansion-coefficient for 50° = ·0563. It forms a double compound with $NaβC^6H^{13}O$ (beta-hexylate of sodium—the body produced by treating β hexylic alcohol with sodium), which double compound is decomposed by water, giving β hexylic alcohol.

Hexyl-alcohols.—*α Hexyl-alcohol* (caproic alcohol), α $C^6H^{14}O$, was found by Faget, in fusel-oil (1854), but not purified by him. Cahours and Pelouze obtained it from hydride of hexyl, by converting that compound into α iodide of hexyl, thence forming α acetate of hexyl; thence, by means of caustic potash, the alcohol. The α hexyl-alcohol thus prepared boils at about 150°, and smells like amylic alcohol. (Compt. rend. liv. 1245.)

α hexylic alcohol yields caproic acid by oxidation. (Faget.)

β Hexyl-alcohol, β $C^6H^{14}O$.—Prepared by digesting β iodide of hexyl with oxide of silver and water: the β alcohol is then formed, together with β hexylic ether, and β hexylene. Or better, by shaking up β hexylene with sulphuric acid (previously diluted with one-third its volume of water), by which means β hexyl-sulphuric acid is produced, and this, distilled with a large excess of water, yields β hexyl-alcohol. It is a viscid liquid, having a refreshing, pleasant smell, very unlike that of amylic alcohol; boils at 137°, under bar. pressure of 755·5 millimetres. Specific gravity at 0° = 0·8327; at 16° = 0·8209; at 99° = 0·7482. It therefore expands somewhat rapidly.

Concentrated *sulphuric acid* converts it into para-hexylene, even at 0°, and does not form any hexyl-sulphuric acid, even after standing for some time. More dilute acid (strength about 87 per cent. SO^4H^2) forms β hexyl-sulphuric acid, which is capable of forming salts. *Acid chromate of potassium* and dilute sulphuric acid convert it into an aldehyde, which has no tendency to take up oxygen from the air, and when further oxidised with the same oxidising agent, yields, not caproic acid, but carbonic acid, water, butyric and acetic acids. The β variety of the alcohol has not been converted into the α variety; on the contrary, there is every reason to believe that the two bodies are radically different. (Wanklyn and Erlenmeyer, Chem. Soc. J. xvi. 221.)

Digitized by Google

Hexyl-aldehydes.—*α Hexyl-aldehyde*, α $C^6H^{12}O$.—Unknown: it might perhaps be obtained by oxidation from the α alcohol of fusel-oil, or of that derived from the hexyl-hydride found in petroleum.

β Hexyl-aldehyde, β $C^6H^{12}O$.—Obtained by oxidising the corresponding alcohol with acid chromate of potassium and dilute sulphuric acid. It is a colourless limpid liquid of fragrant, penetrating odour; boils at 127° (bar. = 761·2 millimetres). Specific gravity at 0° = 0·8298, at 50° = 0·7846: coefficient of expansion between 0° and 50° = 0·0576. It forms a solid compound with acid sulphite of sodium; does not reduce ammonio-nitrate of silver; does not take up oxygen from the air. 100 parts of water dissolve about one part of β hexyl-aldehyde. When treated with *acid chromate of potassium* and dilute sulphuric acid, it yields no caproic acid, but butyric, acetic, and carbonic acids, and water (Wanklyn and Erlenmeyer, Chem. Soc. J. xvi. 307). A consideration of these reactions of β hexylic aldehyde leads to the conclusion that it is an acetone; for whilst the aldehydes take up oxygen from the air and yield by oxidation the corresponding acid, the acetones do not take up oxygen from the air, and yield lower acids (when oxidation is brought about).

This view of the case becomes increasingly probable when the history of acetic acetone, lately brought to light by Lieben, is considered. Acetone is reduced by hydrogen to tritylic alcohol; but the tritylic alcohol thus formed yields by oxidation, not propionic aldehyde, but common acetone.

β Hexyl-aldehyde will probably turn out to be either methyl-valeryl, $\left.\begin{matrix}CH^3\\C^5H^9O\end{matrix}\right\}$, or ethyl-butyryl, $\left.\begin{matrix}C^2H^5\\C^4H^7O\end{matrix}\right\}$.

Chlorides of Hexyl.—*α Hexyl-chloride*, α $C^6H^{13}Cl$, is obtained by Pelouze and Cahours, by the action of chlorine upon the hydride of hexyl existing in American petroleum. In addition to the α chloride of hexyl, further substitution-products are obtained. α Chloride of hexyl decomposes an alcoholic solution of *monosulphide of potassium*, giving α sulphide of hexyl, α $(C^6H^{13})^2S$, boiling at 230°. With *sulphydrate of potassium*, it gives hexyl-mercaptan: boiling point 145° to 148°. With *cyanide of potassium*, it seems to give α cyanide of hexyl. (Compt. rend. x. 1241, *et seq.*)

β Hexyl-chloride is obtained by saturating the corresponding alcohol with dry hydrochloric acid, and heating in the water-bath under pressure. It is an oily liquid, lighter than water, boiling at about 120°, and yielding hexylene when digested at 100° with alcoholic solution of potash.

Hydrides of Hexyl.—*α Hexyl-hydride*, α C^6H^{14}, was found by Greville Williams in the products of the distillation of Boghead coal, and called by him (originally) propyl (with which it is isomeric); in 1862 he came to the conclusion that his propyl was hexyl-hydride (Chem. Soc. J. xv. 130). Pelouze and Cahours found the same substance in American petroleum (Compt. rend. liv. 1241), and obtained a chlorine substitution-product from it, which reacted as chloride of hexyl should do. From the chloride was indirectly obtained an alcohol (p. 152) boiling at about 150°, and like amyl-alcohol in odour. Schorlemmer obtained the hydride also from the products of distillation of Cannel coal. Its boiling point is 68°. Density of the liquid = 0·6745 at 18° (Williams); 0·669 at 16° (Pelouze and Cahours); 0·678 at 15·5° (Schorlemmer). The vapour-density corresponds closely with the formula C^6H^{14}. It is a colourless mobile liquid, having a fragrant odour. Chemically, like all bodies of its class, it is very inactive. Neither sulphuric acid nor nitric acid attacks it; chlorine and bromine only with difficulty. In the arts, a mixture of α hydride of hexyl with other hydrides goes by the name of *turpentine substitute*.

β Hexyl-hydride, β C^6H^{14}, is obtained indirectly from mannite. It may be prepared by digesting zinc with β iodide of hexyl and water or alcohol; or by exposing mercury and the iodide to the action of sunlight. In the latter case the reaction is:

$$Hhg + 2C^6H^{13}I = HhgI^2 + C^6H^{12} + C^6H^{14}.$$

In the former case hexylene also accompanies the hydride. In order to remove the hexylene, it is well to shake up with sulphuric acid, which enters into combination with the hexylene.

In smell, boiling point, and outward appearance, the β hydride resembles the α hydride very closely. In specific gravity, however, it appears to differ from the α compound, being lighter. At 16·5° its specific gravity does not exceed 0·6645. Its derivatives are probably quite distinct from those of the α hydride.

Iodides of Hexyl.—*α Hexyl-iodide*, α $C^6H^{13}I$, is obtained by Pelouze and Cahours from hydride of hexyl existing in American petroleum. It boils at 172° to 175° (being of higher boiling point than the β iodide), and smells like iodide of amyl. It is acted upon by light. It reacts with a variety of salts, forming ethers. The

Digitized by Google

alcohol which is indirectly obtained from it boils at 150°, and is believed by Pelouze and Cahours to be identical with Faget's alcohol extracted from fusel-oil (Compt. rend. liv. 1241, *et. seq.*) Wurtz has also obtained a hexyl-iodide by acting with hydriodic acid upon a variety of hexylene which seems to be distinct from the β hexylene of mannite.

β Hexyl-iodide is prepared by boiling mannite with a great excess of the strongest aqueous solution of hydriodic acid in a stream of carbonic anhydride (24 grms. mannite to 300 cub. cent. of acid, boiling at 126° C.); phosphorus may be added to the boiling liquid with great advantage. The iodide of hexyl appears in the form of an oily distillate, which should be freed from iodine and purified by distilling it in contact with water. When the operation is properly performed, very nearly the theoretical quantity of perfectly pure iodide of hexyl is obtained. The change which takes place is represented by:

$$\underset{\text{Mannite.}}{C^6H^8(HO)^6} + 11\,HI = \underset{\text{Iod. hexyl.}}{C^6H^{13}I} + 6H^2O + I^{10}.$$

Melampyrin (ii. 349) may be substituted for mannite in the above process; but the yield is not so good. The β iodide may also be prepared by digesting β hexylene with hydriodic acid.

β Iodide of hexyl is a colourless liquid, not to be distinguished by the smell from iodide of amyl. Specific gravity at 0° = 1·4447; at 50° = 1·3812; its co-efficient of expansion between 0° and 50° is 0·0460. The boiling point at 752 millimetres = 167·5° C. It is only very slightly decomposed by distillation, and is, on the whole, a very stable compound.

The almost invariable product of the reaction of this iodide is hexylene. With alcoholic solution of potash, it has given very nearly the theoretical quantity of hexylene:

$$\beta\,C^6H^{13}I + KHO = \beta\,C^6H^{12} + H^2O + KI.$$

With *oxide of silver* and *water*, *acetate of lead*, *mercury*, *sodium*, *oxalate of silver*, *zinc and water*, or *zinc and alcohol*, and finally, when heated to 190° with *water* alone, it invariably yields considerable quantities of hexylene, other products being formed at the same time, according to the reagent employed.

Bromine acts with great violence, replacing the equivalent of iodine in β iodide of hexyl.

β Hexyl-oxide, $\beta\,\left.\begin{matrix}C^6H^{13}\\C^6H^{13}\end{matrix}\right\}O$ is formed, together with the olefine and alcohol, when moist oxide of silver acts upon the corresponding iodide:

$$Ag^2O + 2\,\beta\,C^6H^{13}I = 2AgI + \beta\,\left.\begin{matrix}C^6H^{13}\\C^6H^{13}\end{matrix}\right\}O.$$

It is a thick, slightly yellow liquid, not miscible with water, and of a faint penetrating smell. Boils constantly between 203·5° and 208·5°, with the barometer at 751 millimetres.

Hexyl-sulphuric acids. — α *Hexyl-sulphuric acid*, $\alpha\,\left.\begin{matrix}C^6H^{13}\\H\end{matrix}\right\}SO^4$, is little known.

β Hexyl-sulphuric acid is obtained by the action of sulphuric acid (diluted with about one-third of its volume of water) either on β hexylene, or on β hexyl-alcohol. It is partially decomposed by dilution with water, and gives off β hexyl-alcohol. Salts of this acid have been obtained.

β Sulphydrate of Hexyl, or *β Hexyl-mercaptan*, is obtained by digesting the β iodide with a concentrated alcoholic solution of sulphydrate of potassium:

$$\beta\,C^6H^{13}I + KHS = \beta\,\left.\begin{matrix}C^6H^{13}\\H\end{matrix}\right\}S + KI.$$

On adding water to the product of the reaction, the mercaptan separates as a clear, colourless, mobile liquid, not miscible with water and lighter than water. β Hexyl-mercaptan is formed *in the theoretical quantity* in this operation. As was mentioned above, an alcoholic solution of hydrate of potassium transforms β iodide of hexyl almost completely into hexylene and water; sulphydrate of potassium, on the other hand, transforms the iodide into β sulphydrate of hexyl. When an alcoholic solution of *sulphide of potassium* is used, there is also no formation of hexylene, but of a β sulphide instead, so that the sulphur-compounds of the β series are much more stable than the corresponding oxygen-compounds.

It is further noteworthy that β hexyl-mercaptan boils at 142° under a bar. pressure of 760 millimetres—being the point at which the α mercaptan ought to boil.

β Hexyl-mercaptan has the kind of smell characteristic of a mercaptan, only it seems not to be so persistent as the smell of common mercaptan. It acts upon oxide of mer-

Digitized by Google

cury with energy. Sodium attacks it, with evolution of a gas and formation of a white residue; no doubt the reaction is of the usual kind:

$$\left.\begin{matrix}\beta\ C^6H^{12}\\ H\end{matrix}\right\}S + Na = \left.\begin{matrix}\beta\ C^6H^{12}\\ Na\end{matrix}\right\}S + H.$$

Very curiously, caustic potash, both solid and in aqueous solution, also attacks this mercaptan; and, still more curiously, a heat of 100° C. decomposes the compound formed with aqueous potash, occasioning separation of the mercaptan, which, however, recombines on cooling. J. A. W.

HEXYLENE. C^6H^{12}.—Of this hydrocarbon there are also two modifications.

α Hexylene. It is doubtful whether Fremy's hydrocarbon, boiling at 55° and obtained by the distillation of hydroleic and metoleic acids, was hexylene. Greville Williams obtained hexylene from the products of the distillation of Boghead coal. It boiled at 71° (Phil. Trans. 1847). Wurtz seems to have obtained a variety of hexylene from fusel-oil.

β Hexylene is formed by the reaction of the corresponding iodide with most reagents. It is best prepared by the action of the iodide upon alcoholic solution of caustic potash, at 100°. In preparing it, the precaution should be taken to distil the alcoholic solution of hexylene from the iodide of potassium produced during the reaction, and to digest the distillate with fresh potash. The alcohol is subsequently removed by washing.

β Hexylene is a very mobile liquid, lighter than, and not miscible with, water. Boiling point 68° to 70°. Its odour is very unpleasant, just like that of amylene. Vapour-density, by experiment, 2·88 and 2·97 (theory requires 2·9022). It combines with *bromine* with great violence, forming $C^6H^{12}Br^2$. With concentrated *sulphuric acid* it gives parahexylene. With sulphuric acid diluted with about one-third its volume of water, it gives β hexyl-sulphuric acid. β Hexylene seems to be a lighter liquid than α hexylene. J. A. W.

HIPPARAFFIN. C^9H^7NO.—A product of the oxidation of hippuric acid, discovered by Schwarz (Ann. Ch. Pharm. lxxv. 201), further investigated by J. Maier, (*ibid.* cxxvii. 161), who has shown that hipparin is formed at the same time. To prepare it, hippuric acid is stirred up to a paste with dilute sulphuric acid, then mixed with peroxide of lead, and left to stand at a gentle heat for 12 to 24 hours. The mass is then washed with cold water; the residue exhausted with alcohol; the alcoholic solution evaporated; the residue washed with carbonate of soda to remove benzoic and undecomposed hippuric acid; and the residue boiled with water, which leaves hipparaffin undissolved and deposits hipparin on cooling. (Maier.)

Hipparaffin crystallises from hot alcohol in extremely soft slender needles, having a silky lustre and arranged in thick interlaced tufts. It has neither taste nor odour; dissolves sparingly in hot, and is quite insoluble in cold *water*, which does not even wet it; the solubility is not increased by addition of sulphuric acid, hydrochloric acid, ammonia or potash. It dissolves in strong *sulphuric acid*, and is precipitated by water without much alteration (Schwarz). Dissolves easily in strong sulphuric and nitric acid, and is not precipitated from either solution by water (Maier). It dissolves readily in boiling *alcohol*, and very readily in *ether*. It melts at 200° (Schwarz), 210° (Maier), solidifying in the crystalline form as it cools. At a higher temperature part of it distils without alteration, the residue turning black (Schwarz); a small quantity sublimes in slender needles even below 100°. (Maier.)

Hipparaffin burns with a bright smoky flame, leaving a small quantity of easily combustible charcoal. It is not decomposed by solution of *iodine*, or by *hydrochloric acid and chlorate of potassium*, or by aqueous *chromic acid*. It is but partially decomposed by fusion with *hydrate of potassium;* but on igniting it with *potash-lime*, benzene is produced, and the whole of the nitrogen is given off in the form of ammonia (Schwarz). Heated to 200°—220° in a stream of *hydrochloric acid gas*, it gives off a colourless oil, which solidifies in the crystalline form. *Fuming nitric acid* dissolves it, with evolution of gas, and the solution, concentrated after neutralisation with soda, yields a precipitate of benzoic acid. Heated with *peroxide of lead* and dilute sulphuric acid, it gives off all its carbon in the form of carbonic anhydride. (Schwarz.)

HIPPARIN. $C^9H^9NO^2$. (J. Maier, *loc. cit.*)—The preparation is given in the preceding article. Hipparin crystallises in large silky needles united in barrel-shaped groups. Melts at 45·7°; solidifies at about 20°; burns with a bright flame; dissolves easily in alcohol, ether, and boiling water.

HIPPOPHAË RHAMNOIDES. The *Sea Buckthorn.*—This plant contains a yellow colouring matter which appears to be identical with quercitrin. It is obtained by exhausting the berries, after they have been well boiled in water and dried, with hot alcohol; mixing the hot filtered liquid with basic acetate of lead; decomposing

Digitized by Google

the precipitate with sulphydric acid; heating the whole; filtering when cold; and treating the precipitated sulphide of lead with hot alcohol. The colouring matter then dissolves, and remains on evaporation, as a brown-red brittle mass still retaining a little fat, from which it may be purified by treatment with ether, absolute alcohol, &c. It is then obtained as a yellow mass containing rudimentary crystals. The berries likewise contain oxalic and malic acids, a peculiar fat, &c., which are extracted by boiling them with water. (Bolley, Dingl. pol. J. clxii. 143; Jahresber. 1861, p. 708.)

HIPPURAMIDE. $C^9H^{10}N^2O^2 = \left.\begin{matrix} C^7H^5O \\ (C^2H^2O)'' \\ H^3 \end{matrix}\right\} N^2$.—This amide is produced by the prolonged action of ammonia on an alcoholic solution of hippurate of methyl, and remains when the solution is evaporated. It dissolves in 100 pts. water at ordinary temperatures, in 80 pts. wood-spirit, and 50 pts. alcohol; sparingly soluble in ether. By alkalis at the boiling heat it is resolved into ammonia and hippuric acid. (Jacquemin and Schlagdenhauffen, Compt. rend. xlv. 1011.)

HIPPURIC ACID. $C^9H^9NO^3 = \left.\begin{matrix} H \\ C^7H^5O \\ (C^2H^2O)'' \\ H \end{matrix}\right\} \begin{matrix} N^* \\ \\ \\ O \end{matrix}$. (Gm. xii. 69; Gerh. iii. 242).—This acid exists in the urine of herbivorous animals, and in smaller quantity in that of man. Rouelle, towards the end of the last century, first observed that the urine of horses contained an acid bearing considerable resemblance to benzoic acid, and the observation was afterwards confirmed by Fourcroy and Vauquelin, who separated the acid by addition of hydrochloric acid; but its real nature and separate identity were first established by Liebig, in 1830 (Ann. Ch. Pharm. xii. 20). The urine of cows and horses does in fact contain, sometimes hippuric and sometimes benzoic acid, the former acid being easily converted into the latter by oxidation; and this change often taking place within the animal organism. When horses are kept in the stable, or only lightly worked, their urine contains hippuric acid; but when they are put to hard work, it contains benzoic acid.

Cows' urine, according to Boussingault, contains about 1·3 per cent. of hippuric acid; in that of horses, the maximum amount is about 0·38 per cent.; that of swine does not appear to contain hippuric acid; that of the camel and elephant yields a considerable quantity.

From the experiments of Henneberg, Stohmann, and Rautenberg (Ann. Ch. Pharm. cxxiv. 181; Rép. Chim. pure 1863, p. 223; Jahresber. 1862, p. 541) it appears that the urine of oxen contains a maximum quantity of hippuric acid (2·1 to 2·7 per cent.) when the animals are fed on oat- and wheat-straw with a small admixture of beans. The straw and dried herb of leguminous plants reduced the amount to 0·4 per cent. With the hay of graminaceous plants intermediate results were obtained. The addition of a certain quantity of beans, starch, sugar, or oil, diminished the proportion of hippuric acid, and increased that of urea.

In human urine, the proportion of hippuric acid is but small under normal conditions, and about equal to that of uric acid (Liebig; Bence Jones); in certain diseases, as in diabetes, according to Lehmann, the amount is considerably greater; a vegetable diet likewise increases it. In the urine of a healthy man living on a mixed diet, Bence Jones (Chem. Soc. J. xv. 81) found, by Liebig's method of estimation (p. 158), from 0·03 to 0·04 per cent. hippuric acid; Thudichum (*loc. cit.* xvii. 55) found the same quantity under similar circumstances; but the amount was largely increased by eating greengages. Weismann (J. pr. Chem. lxxiv. 106; Jahresber. 1858, p. 572) and Wreden (J. pr. Chem. lxxvii. 146; Jahresber. 1859, p. 700) found much larger quantities; but the former appears to have operated on too small a quantity of urine, and the latter adopted a defective method of analysis (p. 159).

Formation.—1. By heating glycocine in a sealed tube with benzoic acid:

$$C^2H^5NO^2 + C^7H^6O^2 = C^9H^9NO^3 + H^2O;$$

also by heating the zinc-salt of glycocine with chloride of benzoyl to 120° in a sealed tube, or by simply leaving the two compounds in contact for some time:

$$C^4H^6ZnN^2O^4 + 2C^7H^5OCl = 2C^9H^9NO^3 + ZnCl^2.$$

This formation of hippuric from benzoic acid likewise takes place when the latter acid is injected into the blood of a living animal, together with glycocine or glycocholate of sodium, or bile. When about 2 grms. of benzoic acid, and 30 c.c. of bile free from mucus were injected into the blood of a dog or cat, the urine was found to contain a considerable quantity of hippuric, but no benzoic acid; with a larger proportion of

* On the rational formula of hippuric acid, see FORMULÆ (ii. 697).

Digitized by Google

benzoic acid, the excess passed into the urine together with the hippuric acid. Benzoic acid injected into the circulation alone, is not converted into hippuric acid. (Kühne and Hallwachs, Jahresber. 1859, p. 638.)

2. Benzoic acid is likewise converted into hippuric acid in the animal organism when introduced into the alimentary canal, hippuric acid being found in the urine after benzoic acid has been swallowed. Marchand, after taking 30 grains of benzoic acid, found 39·2 grs. of hippuric acid in his urine (by calculation, it should have been 44 grs.). Similar observations have been made by Al. Ure (J. Pharm. xxvii. 646), Keller (Ann. Ch. Pharm. xliii. 198), and Garrod (Phil. Mag. [3] xx. 501).

3. Quinic acid is also converted in the animal organism into hippuric acid (probably first into benzoic acid). When 8 grms. of quinate of calcium were swallowed over night, the morning urine was found to contain 2 grms. of hippuric acid. (Lautemann, Ann. Ch. Pharm. cxxv. 9.)

Preparation from horses' or cows' urine.—Hippuric acid exists in the urine in combination with ammonia. To obtain it, the fresh urine of cows or of horses which have been kept at rest, is concentrated by evaporation to $\frac{1}{6}$ or $\frac{1}{8}$ of its bulk and supersaturated with hydrochloric acid; it then, after a while, deposits a yellowish-brown precipitate of hippuric acid.

The evaporation of the urine, which is tedious, may be obviated by mixing it with a considerable excess of hydrochloric acid, the solubility of the hippuric acid being thereby greatly diminished. 100 pts. of cows' urine mixed with 2 or 3 pts. of crude hydrochloric acid soon deposits hippuric acid (Riley, Chem. Soc. Qu. J. v. 97). Another mode of expediting the process is to mix the fresh urine with milk of lime, boil for a few minutes and strain; then evaporate the solution of hippurate of calcium to $\frac{1}{8}$ or $\frac{1}{12}$ of its bulk, according to the previous concentration; and supersaturate with hydrochloric acid. (Gregory, Ann. Ch. Pharm. lviii. 125.)

The acid obtained as above has a brownish colour and disagreeable urinous odour, and requires further purification. This may be effected in several ways: 1. Schwarz (Ann. Ch. Pharm. liv. 29) boils the crude acid with milk of lime, which removes the greater part of the fibrin with which it is contaminated; precipitates the filtrate with carbonate of sodium, then boils and filters again, and mixes the filtrate with solution of chloride of calcium, the carbonate of calcium thereby precipitated carrying down the colouring matter; then filters a third time, and precipitates with hydrochloric acid. The hippuric acid thus purified is quite colourless.—2. The crude acid, mixed with 10 pts. of boiling water and excess of milk of lime, is submitted to pressure; the expressed liquid is mixed with solution of alum till it no longer exhibits an alkaline reaction, and left to cool to 40°; carbonate of sodium is then added as long as a precipitate continues to form; and the liquid is again separated by straining and pressure, and precipitated by hydrochloric acid: the hippuric acid thus obtained is washed with cold water, pressed and dissolved in boiling water, and the solution is mixed with blood-charcoal (1 oz. to a lb. of the acid), filtered through paper while still at the boiling heat, and left to crystallise (Bensch, Ann. Ch. Pharm. lviii. 267).—3. Löwe prepares hippuric acid by mixing fresh horse-urine with excess of sulphate of zinc; evaporating the liquid together with the precipitate to $\frac{1}{6}$ or $\frac{1}{8}$ of its bulk; filtering quickly; washing the precipitate with a small quantity of hot water; and decomposing the hippurate of zinc in the filtrate with dilute sulphuric or hydrochloric acid. Hippuric acid then separates in the form of a white magma, which may be washed with cold water, pressed between paper, and recrystallised from boiling water. The addition of sulphate of zinc to the urine preserves it from putrefaction, and enables the experimenter to wait till a considerable quantity is collected.

Properties.—Hippuric acid forms colourless transparent prisms, having an unctuous adamantine lustre, and often of considerable size. The crystals belong to the trimetric system. Ordinary combination, $\infty P . \breve{P}\infty . \breve{P}\infty$. with the modifying faces $\infty\breve{P}\infty$ and $\infty\breve{P}\infty$. Ratio of the axes, $a : b : c = 0{\cdot}9742 : 1{\cdot}1606 : 1$. Inclination of the faces: $\infty P : \infty P$ in the brachydiagonal principal section $= 99° 59'$; $\breve{P}\infty : \breve{P}\infty = 98° 30'$; $\breve{P}\infty : \breve{P}\infty$ in the macrodiagonal principal section $= 88° 30'$. Cleavage tolerably easy, parallel to oP. Specific gravity $= 1{\cdot}308$. Hippuric acid melts at a gentle heat, and solidifies in a crystalline mass on cooling. It has a slightly bitter taste, and reddens litmus strongly. It is sparingly soluble in cold *water*, 1 pt. of the crystals requiring 600 pts. of water at 0°. Boiling water and *alcohol* dissolve it readily; *ether* scarcely at all. Hippuric acid likewise dissolves, but very sparingly, in water containing *hydrochloric acid*. It dissolves with the greatest facility in water containing ordinary *phosphate of sodium*, in such quantity indeed as to change the reaction of the solution from alkaline to acid—a property which is also possessed by uric acid. This, according to Liebig, is the cause of the acid reaction exhibited by the urine of man and other animals in the recent state.

Decompositions.—1. Hippuric acid boils at 240°, yielding a crystalline product, con-

Digitized by Google

sisting in great part of benzoic acid and benzonitrile (cyanide of phenyl); a strong odour of hydrocyanic acid is likewise evolved, and a considerable quantity of charcoal remains in the retort. Dry hippuric acid, heated in a retort with dry chloride of zinc and quartz-sand, yields benzonitrile, carbonic anhydride, and charcoal (Gössmann, Ann. Ch. Pharm. c. 69):

$$2C^9H^9NO^3 - 4H^2O = 2C^7H^5N + CO^2 + C^3.$$

2. Hippuric acid in alkaline solution is slowly oxidised by *ozone*, with formation of carbonic acid and a small quantity of formic acid (Gorup-Besanez, Ann. Ch. Pharm. cxxv. 217).—3. Pure hippuric acid is not altered by boiling with *water*; but when horse-urine is quickly evaporated, ammonia is given off, and the hippuric acid contained in it is converted into benzoic acid. Cows' urine does not yield benzoic acid when boiled.—4. Hippuric acid dissolves in strong *hydrochloric acid* at the boiling heat, and on continuing the ebullition, it is resolved into benzoic acid and glycocine:

$$\underset{\text{Hippuric acid.}}{C^9H^9NO^3} + H^2O = \underset{\text{Glycocine.}}{C^2H^5NO^2} + \underset{\text{Benzoic acid.}}{C^7H^6O^2}.$$

The same decomposition is effected by boiling dilute *sulphuric acid*, by *nitric*, and even by *oxalic acid*.—5. Hippuric acid, boiled for half-an-hour with caustic *potash* or *soda*, is converted into glycocine and an alkaline benzoate. It is not decomposed by boiling with milk of lime.—6. The resolution of hippuric acid into benzoic acid and glycocine is likewise effected by the action of a *ferment* in presence of an alkali (Buchner, Ann. Ch. Pharm. lxxviii. 203).—7. By the action of *nascent hydrogen*, it appears to be resolved into hydride of benzoyl and glycocine (Erlenmeyer, Zeitschr. Ch. Pharm. 1861, p. 548).—8. *Nitrous acid* converts hippuric acid into benzoglycollic acid, with evolution of nitrogen gas:

$$2C^9H^9NO^3 + N^2O^3 = 2C^9H^8O^4 + H^2O + N^4.$$

This decomposition takes place when nitric oxide is passed into a solution of hippuric acid in nitric acid.—9. A cold mixture of strong *sulphuric acid* and fuming *nitric acid* converts hippuric acid into nitrohippuric acid. With *sulphuric anhydride*, it unites directly, forming sulphohippuric acid, $C^9H^9NSO^6$.—10. An aqueous solution of hippuric acid is not decomposed by *chlorine* gas; but on boiling it with a large excess of *bleaching powder*, decomposition takes place (Liebig). When chlorine is passed into a solution of hippuric acid in rather dilute potash, nitrogen is evolved, and benzoglycollic acid is produced (Gössmann):

$$C^9H^9NO^3 + 3KHO + Cl^2 = C^9H^8O^4 + 2H^2O + 3KCl + N.$$

11. By mixing it with *hydrochloric acid*, and adding *chlorate of potassium* by small portions, it is converted into a mixture of monochlorohippuric acid, $C^9H^8ClNO^3$, and dichlorohippuric acid, $C^9H^7Cl^2NO^3$ (R. Otto, Ann. Ch. Pharm. cxxii. 129).—12. When hippuric acid is gently heated with 1 at. *pentachloride of phosphorus*, oxychloride of phosphorus and hydrochloric acid are given off, and a brown residue is left, soluble in alcohol and in ammonia, and precipitated therefrom in the resinous state by hydrochloric acid; but on distilling 1 at. hippuric acid with 2 at. pentachloride of phosphorus, the products obtained are oxychloride of phosphorus, chloride of benzoyl, and two chlorinated compounds, $C^9H^6ClNO^2$, and $C^9H^5Cl^2NO^2$, differing from mono- and dichlorohippuric acids respectively by 1 at. H^2O (Schwanert, see p. 161).—13. When hippuric acid is boiled with *peroxide of manganese* and very dilute sulphuric acid, a large quantity of carbonic anhydride is evolved, benzoic acid separates on cooling, and the liquid is found to contain sulphate of ammonium.—14. Hippuric acid, boiled with *peroxide of lead* and water, yields benzamide, water, and carbonic anhydride (Fehling):

$$C^9H^9NO^3 + 3O = C^7H^7NO + H^2O + 2CO^2.$$

When hippuric acid is heated with peroxide of lead and excess of nitric or sulphuric acid, the products formed are carbonic anhydride and hipparaffin (p. 154); but when it is boiled with water and peroxide of lead, and sulphuric acid added in quantity only sufficient to decompose the resulting hippurate of lead, the only product obtained is benzamide (Schwartz).—15. Hippuric acid, gently heated with excess of caustic *baryta*, yields a liquid which smells of benzene (no ammonia is evolved), is converted into crystalline scales by contact with hydrochloric acid, and, when distilled, yields pure benzene (Gerhardt). This liquid is perhaps benzonitrile.

Estimation of Hippuric acid in urine.—1. The urine is evaporated to a syrupy consistence over a water-bath; hydrochloric acid is added; and the hippuric acid is extracted by treating the precipitate four or five times with ether (Liebig, Ann. Ch. Pharm. l. 170). According to Bence Jones (Chem. Soc. J. xv. 81), this method gives exact results, provided sufficient urine is taken (about 400 c. c.), and a sufficient quantity of ether is used. Thudichum (Chem. Soc. J. xvii. 55) evaporates the urine to

Digitized by Google

a stiff syrup, pours it into a bottle while yet warm, taking up the last residues with the necessary amount of hydrochloric acid; and shakes up the whole briskly with large quantities of dry ether. The ethereal solution is then distilled, the reddish yellow residue mixed with a little water, and allowed to crystallise; and the crystals of hippuric acid thus obtained are washed with water till the washings are colourless, then dried by pressure between blotting paper, afterwards by placing them over sulphuric acid, and finally at 100° in a water-oven. (See also Weismann, J. pr. Chem. lxxiv. 106; Jahresber. 1857, p. 637.)

2. Wreden (J. pr. Chem. lxxvii. 446; Jahresber. 1859, p. 700) estimates hippuric acid in urine by means of a standard solution of ferric chloride. The liquid is first neutralised and freed from phosphoric acid by means of baryta-water, and the iron solution is added till it no longer forms a precipitate, and a drop of the filtered solution produces a blue colour on a piece of filtering paper moistened with ferrocyanide of potassium. The amount of hippuric acid found in human urine by this method of estimation (average 0·38 per cent.) is much higher than that determined by Liebig's method (p. 156); and, according to Henneberg, Stohmann, and Rautenberg (Ann. Ch. Pharm. cxxiv. 181), the results are vitiated by the fact that a perfectly neutral solution of ferric chloride is decomposed by paper-fibre to such an extent, that paper soaked in a solution of yellow prussiate will not indicate the presence of a small quantity of iron; also, because the termination of the reaction cannot be distinctly perceived. Better results are obtained with ferric nitrate, after the urine has been freed from colouring matter and other bodies by nitrate of lead; but even in this case the process is sometimes rendered uncertain by the presence of other substances which exert a reducing action on the ferric oxide. Altogether, the mode of estimation by means of hydrochloric acid and ether appears to give the best results.

Hippurates. Hippuric acid is monobasic, the general formula of its salts being $C^9H^8MNO^3$. Most metallic oxides dissolve readily in the acid. The hippurates of potassium, sodium, ammonium and magnesium are very soluble and difficult to crystallise; their solutions form a cream-coloured precipitate with ferric salts, and white curdy precipitates with nitrate of silver and mercurous nitrate. A characteristic reaction of the hippurates is, that when fused with excess of potash or lime, they give off ammonia and yield benzene by distillation. Mineral acids decompose them, separating the hippuric acid.

Hippurate of Ammonium.—The *neutral salt* does not appear to exist. *An acid* salt, $C^9H^7(NH^4)NO^3.C^9H^9NO^3.H^2O$, is produced even when hippuric acid is mixed with excess of ammonia. It crystallises by concentration in square-based prisms with 4-sided summits. It dissolves in small quantities of water and alcohol, sparingly in ether, and performs gyratory movements when thrown on the surface of water.

Hippurate of Barium, $C^{18}H^{16}Ba''N^2O^6 + H^2O$, forms prisms with rectangular base; soluble in water. It unites with benzoate of barium, forming a salt containing $C^{18}H^{16}Ba''NO^6.C^{14}H^{10}Ba''O^4 + 5H^2O$.

Hippurate of Calcium, $C^{18}H^{16}Ca''N^2O^6 + 3H^2O$, crystallises sometimes in rectangular prisms, sometimes in laminæ. Specific gravity 1·318. It is soluble in 18 pts. of cold and 6 pts. of hot water.

Hippurate of Cobalt, $C^{18}H^{16}Co''N^2O^6.5H^2O$, forms rose-coloured needles or nodules, which give off their water at 100°.

Hippurate of Copper, $C^{18}H^{16}Cu''N^2O^6 + 3H^2O$, obtained by concentrating a mixture of sulphate of copper and hippurate of potassium, forms oblique rhomboïdal prisms of an azure-blue colour, which turn green and give off their water of crystallisation when heated on the water-bath.

Hippurate of Iron (ferricum) is precipitated on mixing the concentrated solutions of hippurate of potassium and ferric chloride.

Hippurate of Lead, $C^{18}H^{16}Pb''N^2O^6 + 2H^2O$ and $3H^2O$, is obtained by precipitating a cold solution of neutral acetate of lead with hippurate of potassium, as a curdy precipitate which dissolves but slowly in boiling water. If the boiling solution is well diluted, the salt is deposited in silky needles (containing 1 at. water) grouped in tufts; but these crystals, even when immersed in the solution, are quickly converted into rather broad, shining laminæ ($3H^2O$) having the form of quadrangular tables. The whole of the water is given off at 100°.

Hippurate of Magnesium, $C^{18}H^{16}Mg''N^2O^6 + 5H^2O$, forms white nodules, which are soluble in water and give off $2H^2O$ at 100°.

Hippurate of Nickel, $C^{18}H^{16}Ni''N^2O^6 + 5H^2O$, is crystallisable, insoluble in ether, sparingly soluble in cold water, more soluble in boiling water and in boiling alcohol. It becomes anhydrous at 100°.

Hippurate of Potassium.—The *neutral* salt, $C^9H^8KNO^3.H^2O$, forms oblique prisms with rhomboïdal base, soluble in water and in alcohol, and becoming anhydrous by

Digitized by Google

desiccation at 100°. To obtain it pure, it must be crystallised several times from alcohol and washed with ether.

The *acid* salt, $C^9H^8KNO^3.C^9H^9NO^3.H^2O$, forms brilliant laminæ, which under the microscope are seen to consist of prisms with rectangular base, and the terminal edges truncated. They give off 4·77 per cent. water at 100°.

Hippurate of Silver, $2C^9H^8AgNO^3.H^2O$, prepared by adding nitrate of silver to hippurate of potassium, is soluble in water and crystallisable. It gives off its water (3·42 per cent.) at 100°.

Hippurate of Sodium, $2C^9H^8NaNO^3.H^2O$, is crystallisable, very soluble in hot water and in alcohol, sparingly in ether.

Hippurate of Strontium, $C^{18}H^{16}Sr''N^2O^6.5H^2O$, is crystallisable; sparingly soluble in cold water and alcohol; gives off its water at 100°.

Derivatives of Hippuric Acid.

Amido-hippuric acid. $C^9H^{10}N^2O^3 = C^9H^8(NH^2)NO^3$. (Schwanert, Ann. Ch. Pharm. cxii. 69.)—Obtained by passing sulphydric acid gas for a considerable time into a solution of nitrohippuric acid in saturated sulphide of ammonium, and acidulating the concentrated liquid with hydrochloric, or better with nitric acid. It crystallises in light white laminæ, soluble in 300 to 370 pts. water at 20°, in 1200 pts. absolute alcohol at 15°, insoluble in ether. In boiling water and alcohol it dissolves easily; likewise in acids and in alkalis; the solutions quickly turn brown. With concentrated hydrochloric acid, it forms a *hydrochlorate* containing $C^9H^{10}N^2O^3.HCl$.

Chlorohippuric acids. (R. Otto, Ann. Ch. Pharm. cxxii. 129.)—These compounds are produced by the action of hypochlorous acid on hippuric acid. When 2 or 3 pts. chlorate of potassium are added to a mixture of 1 pt. hippuric acid and 6 to 9 pts. hydrochloric acid, a gentle heat applied, after the frothing has ceased, to complete the reaction, the liquid then heated to boiling and left to cool,—an oily yellowish mass is deposited, consisting of mono- and dichlorohippuric acids, their relative quantities depending, partly on the quantity of chlorate used, partly on the temperature of the liquid during the reaction. The two acids are separated, either by boiling with water, which dissolves chiefly the monochlorinated acid, or by repeated crystallisation of the calcium-salts obtained by neutralising the mixed acids with milk of lime.

Monochlorohippuric acid, $C^9H^8ClNO^3$, obtained by evaporating the alcoholic solution, after decolorisation with animal charcoal, forms a yellowish, viscid, inodorous mass, having an acid reaction; it is nearly insoluble in cold water, melts and dissolves in boiling water, and mixes in all proportions with alcohol and ether. It dissolves also in caustic alkalis, forming a solution which turns brown when heated.—By boiling with concentrated hydrochloric acid, it is resolved into glycocine and monochlorobenzoic acid.

The *neutral potassium-* and *sodium-salts* are uncrystallisable or crystallise with difficulty. The *acid sodium-salt*, $2(C^9H^7ClNaNO^3.C^9H^8ClNO^3).H^2O$, crystallises in concentrically grouped needles.—The *calcium-salt*, $C^{18}H^{14}Cl^2Ca''N^2O^6.4H^2O$, crystallises from alcohol in small shining scales.—The *lead-salt*, $C^{18}H^{14}Cl^2Pb''N^2O^6$, melts at 100—120°, and crystallises from dilute alcohol in concentrically grouped needles.—The *silver-salt* is a white precipitate, which crystallises indistinctly from solution in water.

Dichlorohippuric acid, $C^9H^7Cl^2NO^3$, is very much like the monochlorinated acid, and after standing in contact with the air or under water, forms a soft granulo-crystalline mass, which deliquesces when warmed, and at 60° emits an aromatic turpentine-like odour.—By boiling with strong hydrochloric acid, it is resolved into glycocine and dichlorobenzoic acid.

Dichlorohippurate of sodium, $C^9H^6Cl^2NaNO^3.H^2O$, forms soft warty crystals, easily soluble in water, alcohol, and acids.—The *barium-salt*, $C^{18}H^{12}Cl^4Ba''N^2O^6.3H^2O$, crystallises in needles.—The *calcium-salt*; $C^{18}H^{12}Cl^4Ca''N^2O^6$, crystallises from dilute solutions at ordinary temperatures, or at 60°, in needles containing 9 or 10 at. water; at higher temperatures, in hard white crusts with 5 at. water.—The *neutral lead-salt*, $C^{18}H^{12}Cl^4Pb''N^2O^6.4H^2O$, obtained by cold precipitation, separates from its aqueous solution in nodules. A *basic lead-salt*, $2C^{18}H^{12}Cl^4Pb''N^2O^6.Pb''O.6H^2O$, may be extracted by boiling absolute alcohol from the precipitate formed by dichlorhippuric acid and acetate of lead at the boiling heat. The *silver-salt* is a white precipitate, which separates from hot water in cauliflower-like masses.

Dichlorohippurate of Ethyl, $C^9H^6Cl^2(C^2H^5)NO^3$, obtained by treating the alcoholic solution of the acid with hydrochloric acid gas, is a heavy yellowish oil, nearly insoluble in water.

A *calcium-salt* having the composition, $C^{18}H^{13}Ca''Cl^3N^2O^6.5H^2O$, intermediate between the mono- and dichlorohippurates, is obtained in spherical groups of needles by crystallising a mixture of the calcium-salts of the two acids. Its solution precipitated by nitrate of silver yields a *silver-salt* of analogous composition.

evaporating, sulphohippuric acid is obtained as a brownish yellow, amorphous, deliquescent mass.

With *nitrous acid* it forms (not sulphobenzoglycollic, but) sulphobenzoic acid, $C^7H^6SO^5$, together with an oily substance probably containing glycollic acid.

Sulphohippuric acid is dibasic. Its neutral *barium-salt* contains $C^9H^7Ba''NSO^6.H^2O$. By boiling the acid with hydrate of lead, a *lead-salt* is obtained corresponding approximately with the formula $C^9H^7Pb''NSO^6$.

HIPPURIC ETHERS. Only two of these compounds have as yet been obtained, viz. the ethylic and methylic ethers.

Hippurate of Ethyl. $C^{11}H^{13}NO^3 = C^9H^8(C^2H^5)NO^3$. (Stenhouse, Ann. Ch. Pharm. xxxi. 148.)—Prepared by passing hydrochloric acid gas through a boiling solution of hippuric acid in alcohol of 80 per cent. The liquid thickens, assumes an oily aspect, and when diluted with water, deposits the ether in liquid drops, which soon solidify.

Hippurate of ethyl is crystallisable and has a sharp taste. Specific gravity 1·043. Melts at 44° and solidifies at 32° C. Sparingly soluble in water, very soluble in alcohol. Chlorine, with the aid of heat, converts it into a crystallisable chlorinated compound. Nitric and sulphuric acids decompose it at the boiling heat, producing benzoic acid. Alcoholic potash converts it into ethylic alcohol and hippurate of potassium.

Hippurate of Methyl. $C^{10}H^{11}NO^3 = C^9H^8(CH^3)NO^3$. (Jacquemin and Schlagdenhauffen, Compt. rend. xlv. 1011.)—Prepared by passing hydrochloric acid gas into a soluton of the acid in wood-spirit heated to 50° or 60° C., washing the resulting syrupy liquid with carbonate of sodium, and then treating it with ether, from which the compound crystallises by spontaneous evaporation.

Hippurate of methyl forms white, transparent needles, soluble in 120 pts. of cold water, and in 60 pts. water at 30°; in boiling water it melts before dissolving. Alcohol and ether dissolve it in all proportions. It melts at 60° and decomposes at 250°, giving off ammonia and benzonitrile. With fuming nitric acid it gives off a combustible gas, probably containing nitrate of methyl. Alkalis decompose it, forming hippuric acid and methylic alcohols. Ammonia converts it into hippuramide.

HIRCIC ACID. The name given by Chevreul (*Recherches sur les corps gras*, pp. 151, 236) to an oily acid, slightly soluble in water, which he obtained from mutton-suet, and to which he attributes the peculiar taste and odour of that substance. The *potassium-salt* is very deliquescent; the *barium-salt* is sparingly soluble in water and contains 43·8 per cent. barium. The acid is probably nothing more than a mixture of several acids of the series $C^nH^{2n}O^2$.

HISINGERITE. A hydrated silicate of iron occurring at Ridharhyttan in Sweden and other localities. A variety called *Gillingite* is found in the Gillinge mine at Svärta-Kirchspiel in Sweden, and another called Thraulite at Bodenmais in Bavaria. These minerals all contain both protoxide and sesquioxide of iron, and are closely allied in composition; they are, however, but imperfectly crystallised, and have a dark colour, so that impurities in them easily escape detection. Moreover, it is possible that part of the protoxide of iron in the original mineral may be gradually converted into sesquioxide. Hence their constitution cannot be ascertained with certainty. The composition of hisingerite from Ridharhyttan (specific gravity 3·045) agrees however nearly with the formula $3(FeO.SiO^2).2(Fe^2O^3.3SiO^2) + 6H^2O$. Gillingite is the same with 9 at. water; Thraulite is $3(FeO.SiO^2).(Fe^2O^3.3SiO^2) + 6H^2O$. A variety from Orijärfvi in Finland, much richer in protoxide of iron, may be represented by the formula $9(FeO.SiO^2).(Fe^2O^3.3SiO^2) + 9H^2O$. The following are analyses of these minerals:

	SiO^2	Fe^2O^3	FeO	CaO	MgO	H^2O	
a.	33·07	34·78	17·59	2·56	0·46	11·54	= 100·0
b.	32·18	30·10	8·63	5·50	4·22	19·37	= 100·0
c.	31·28	49·12		. .	. .	19·12	= 99·52
d.	29·51	10·74	37·49	. .	7·78	13·00	= 98·52

a, from Ridharhyttan by Rammelsberg (*Mineralchemie*, p. 852).—*b*, from the Gillinge mine by Rammelsberg (*ibid.*).—*c*, Thraulite from Bodenmais by v. Kobell (Pogg. Ann. xiv. 467).—*d*, from Orijärfvi by Hermann. (J. pr. Chem. xlvi. 338.)

HISLOPITE. A grass-green limestone from Takli near Nágpur in Central India, of specific gravity 2·645, and containing 80·79 per cent. carbonate of calcium, 0·73 alumina, a trace of carbonate of magnesium, and 16·63 of an imbedded green silicate (= 98·15), perhaps identical with glauconite. (S. Haughton, Phil. Mag. [4] xvii. 16.)

HITCHCOCKITE. A silicate of lead and aluminium from the Canton mine in Georgia. Specific gravity, 4·024. Contains 20·85 per cent. P^2O^4, 27·40 PbO, 28·41

Digitized by Google

Al^2O^3, 0·14 $PbCl^2$, and 23·20 water (= 100·00), agreeing nearly with the formula, $3PbO.P^2O^5.2[4Al^2O^3.P^2O^5.18H^2O] = Pb^3P^2O^8.2[(Al^2)^{vi}P^2O^8.3(Al^2)^{vi}H^6O^6] + 18H^2O$. (Genth, Sill. Am. J. [2] xxiii. 424.)

HJELMITE. A mineral consisting chiefly of tantalate of yttrium and iron, found in the neighbourhood of Ytterby, together with garnet, gadolinite, &c. in a rock consisting of quartz, orthoclase, albite, and mica. It has a metallic lustre, granular fracture, pure black colour in the mass, blackish grey in powder. Hardness = 5. Specific gravity = 5·82. It exhibits no distinct indications of crystalline form or cleavage. Its analysis gave:

Ta^2O^5	SnO^{2*}	CuO	CaO	YO	CeO	UO	FeO	MnO	MgO	H^2O
62·42	6·56	0·10	4·26	5·19	1·07	4·87	8·06	3·32	0·26	3·26 = 99·37

Before the blowpipe it decrepitates and flies to pieces, gives off water, and turns brown without melting, in the oxidising flame; by phosphorus-salt it is easily dissolved to a bluish-green glass; easily also by borax to a clear glass rendered opaque by flaming; by reduction on charcoal with carbonate of sodium, it yields metallic spangles. (Nordenskiold, Pogg. Ann. cxi. 273; Jahresber. 1860, p. 780.)

HOERNESITE. A hydrated arsenate of magnesium from the Bannat, found imbedded in calcspar. It forms rhomboïdal laminæ of 36° and 144°, bevelled on the sides, closely resembling the most common form of gypsum, and probably belonging to the monoclinic system, cleaving perfectly in the direction of the pinacoïdal face, having a mother-of-pearl lustre on the cleavage-faces; white, transparent (translucent in the thicker parts), flexible in thin layers. Hardness = 0·5. Specific gravity = 2·474. Splinters of it melt even in the flame of a candle. An analysis by v. Hauer (Rép. Chim. pure, ii. 286) gave 24·54 per cent. MgO, 46·33 As^2O^5, and 29·07 water (= 99·94), agreeing with the formula, $Mg^3As^2O^8.8H^2O$. (Haidinger, Wien. Akad. Ber. xi. 18.)

HOLCUS LANATUS. For the composition of the ash of this grass, see GRASSES (ii. 943).

HOLMESITE. See CLINTONITE (i. 1026).

HOMEOMORPHISM. See ISOMORPHISM.

HOMICHLIN. A mineral closely related to barnhardtite (i. 508), and copper pyrites (ii. 77), from Plauen in the Saxon Voigtland (and other localities), where it forms, together with carbonate and silicate of copper, a vein of copper-ore imbedded in greenstone. It occurs sometimes in quadratic crystals, but more generally massive. Hardness between 4 and 5. Specific gravity = 4·472 to 4·480. Colour, brass-yellow, but with more of a bronze tint than copper-pyrites, and quickly acquiring a many-coloured tarnish. Streak black. According to an analysis by Richter, it contains 25·81 per cent. iron, 43·76 copper, and 30·21 sulphur, agreeing with the formula, $3Cu^2S.Fe^2S^3.2FeS$. (Breithaupt, Sill. Am. J. [2] xxviii. 132; xxix. 373. *Rammelsberg's Mineralchemie*, pp. 426, 987.)

HOMOCUMINIC ACID. $C^{11}H^{14}O^2 = \left.\begin{matrix}C^{11}H^{13}O\\H\end{matrix}\right\}O$. *Cyminic acid.* (Rossi, Compt. rend. lii. 403; Ann. Ch. Pharm. Suppl. i. 139.)—An acid homologous with cuminic acid, prepared by treating cyanide of cymyl, $C^{10}H^{13}Cy$ (obtained by the action of cyanide of potassium on the chloride, ii. 296), with potash-ley at the boiling heat:

$$C^{10}H^{13}.CN + 2H^2O = C^{10}H^{14}O^2 + NH^3.$$

It crystallises in small needles; melts at 52°; distils without decomposition; dissolves sparingly in cold, easily in boiling water, also in alcohol and ether, reddens litmus and decomposes carbonates. The *potassium-salt* is deliquescent; the *barium-* and *calcium-salts* crystallise in needles; the *magnesium-salt* in nacreous scales; the *silver-salt* has the composition $C^{10}H^{13}AgO^2$.

The low melting point of this acid raises a doubt as to whether it is the true homologue of cuminic acid (which melts at 92°) or an isomer of that homologue related to it in the same manner as the acid $C^8H^8O^2$, obtained by Cannizzaro from cyanide of benzyl (probably α-toluylic acid), is related to the true toluylic acid.

HOMOLACTIC ACID. This name was given by Cloez (Compt. rend. xxxiv. 364) to an acid, isomeric if not identical, with glycollic acid, found in the mother-liquor which is obtained in the preparation of fulminating mercury. By neutralising this liquor with chalk, distilling off the volatile products (acetic ether, &c.), repeatedly crystallising the remaining solution by spontaneous evaporation, and decanting the liquid containing the more soluble salts, the calcium-salt of this acid was obtained in small light nodules resembling lactate of calcium.—The acid itself formed, when com

* With tungstic anhydride.

Digitized by Google

centrated, a syrup which did not crystallise. The silver-salt crystallised in long thin laminæ, sparingly soluble in cold water.

HOMOLOGOUS SUBSTANCES. This term is applied to organic compounds differing from one another in composition by CH^2 or any multiple thereof; for example, the *alcohols* $C^nH^{2n+2}O$, the *fatty acids* $C^nH^{2n}O^2$, and the *aromatic acids* $C^nH^{2(n-4)}O^2$.—Bodies thus related exhibit, for the most part, a regular gradation of properties, both physical and chemical. Thus, in the series of fatty acids, formic acid, CH^2O^2, and acetic acid, $C^2H^4O^2$, are watery liquids without any trace of viscosity; propionic acid, $C^3H^6O^2$, is slightly oily; butyric acid, $C^4H^8O^2$, valeric acid, $C^5H^{10}O^2$, and a considerable number of others exhibit more and more of an oily or fatty character as their atomic weights increase; while palmitic acid, $C^{16}H^{32}O^2$, and stearic acid, $C^{18}H^{36}O^2$, and a few others, are at ordinary temperatures solid fats, exhibiting higher melting points as they rise higher in the series; and lastly cerotic acid, $C^{27}H^{54}O^2$, and melissic acid, $C^{30}H^{60}O^2$, are of the consistence of wax. Similar relations are observed in the series of alcohols, corresponding with these acids. Moreover, the chemical energy of bodies thus related continually decreases as their molecules become heavier. Common alcohol is violently decomposed by potassium and sodium, with rapid evolution of hydrogen; but on the fatty alcohols, these metals act but very slowly. Similar differences of character are observed between the higher and lower terms of the fatty acid series. Formic and acetic acids are highly corrosive liquids, which unite energetically with bases, and decompose carbonates with the greatest ease; whereas the solid fatty acids, stearic, palmitic acid, &c., exert no action on the animal tissues, do not enter readily into direct combination with any bases excepting the strongest, and decompose carbonates but slowly.

Bodies belonging to the same homologous series exhibit, for the most part, regular gradations of boiling point and of atomic volume. With regard to the latter, Kopp has shown that compounds whose chemical formulæ differ by n CH^2, differ in atomic volume by $n.22$ (i. 444). The relations of boiling point exhibited by homologous liquids are fully detailed in the article HEAT (p. 89).

Various attempts have been made of late years to build up the terms of homologous series, the higher from the lower. Frankland and Kolbe in 1847 (Ann. Ch. Pharm. lxv. 288) showed that a cyanide of an alcohol-radicle of the series C^nH^{2n+1}, may be converted into the next higher acid by boiling with aqueous potash, the action consisting in the assumption of the elements of water, with elimination of ammonia, *e.g.*:

$$\underset{\text{Cyanide of methyl.}}{CH^3.CN} + 2H^2O = \underset{\text{Acetic acid.}}{C^2H^4O^2} + NH^3;$$

and generally

$$C^nH^{2n+1}.CN + 2H^2O = C^{n+1}H^{2n+2}O^2 + NH^3.$$

Another method of passing from an alcohol to the next higher acid was discovered in 1859 by Wanklyn (Proc. Roy. Soc. x. 21), who showed that sodium-ethyl (prepared from zinc-ethyl, which is itself obtained from iodide of ethyl, and this from ethylic alcohol) exposed to the action of carbonic anhydride, absorbs that gas, and is converted into propionate of sodium:

$$C^2H^5Na + CO^2 = C^3H^5NaO^2.$$

Neither of these reactions, however, affords the means of obtaining one alcohol of the series from the next below it, because no method has yet been discovered of converting a fatty acid into the corresponding alcohol.

The great problem of passing from one alcohol to that next above it has, however, been solved in a general way by Mendius (Ann. Ch. Pharm. cxxi. 129), whose method consists in exposing the cyanides of the alcohol-radicles to the action of nascent hydrogen, thereby converting them into the amines of alcohol-radicles higher than the radicles started from. In this manner, starting from hydrocyanic acid, he obtains methylamine, thus:

$$\underset{\text{Cyanide of hydrogen.}}{HCN} + H^4 = \underset{\text{Methylamine.}}{CH^5N}$$

Methylamine treated with nitrous acid yields methylic alcohol (see AMINES, i. 174); this compound may be converted by well-known processes into cyanide of methyl; and this cyanide treated with nascent hydrogen yields ethylamine:

$$\underset{\text{Cyanide of methyl.}}{CH^3.CN} + H^4 = \underset{\text{Ethylamine.}}{C^2H^7N}.$$

From this last compound, by similar processes, we may ascend to the tritylic or propylic stage, and thus, by a repetition of the same reactions, the series of alcohols

Digitized by Google

y step. The general equation representing the this series to the next highest amine is:

$$+ H^4 = C^{n+1}H^{2n+5}N.$$

y be found to succeed with cyanides derived from eries, and thus a general method of producing an xt below it may be obtained.

$$= C^4H^8Br^2 + 2HBr.$$

th dibromide of tetrylene, might be converted by ylene; and this by the action of hydriodic acid stillation with potash, tetrylic alcohol might be to give the means of mounting up the series by lemmer, by subjecting ethyl-amyl, $C^2H^5.C^5H^{11}$ $H^{15}.H$), to the action of chloride of iodine, has appears to be identical with chloride of heptyl dicle (p. 144). The problem of ascending from us series appears therefore to be capable of solu-

omology, and the relations between homologous rius (Ann. Ch. Pharm. cxxvi. 210).

mmon bee contains cane-sugar, inverted sugar cose. The proportion of cane-sugar varies with y converted into inverted sugar by the action of ording to Soubeiran (Compt. rend. xxviii. 774), ucose and a dextro-rotatory sugar capable of inver- tallisable sugar, possessing a lævo-rotatory power d sugar. The honey of the *Polybia apicipennis*, tropical America, yields cane-sugar in large crys- 0). The honey of the Mexican honey-ant is, em. Gaz. 1853, 72), a nearly pure solution of in vacuo); it has a slight acid reaction, and the xide of silver like formic acid.

fruit of the hop is formed of small membranous a yellow bitter powder called **lupulin** (*q. v.*), by Yves*, 36 per cent. resin, 12 wax, 11 of a ater and alcohol, 5 tannin, 10 extractive matter e insoluble in water. Yves found in hop-cones n. According to Payen and Chevallier, the pro- t., about 4 per cent. of which consists of minute lting from the sifting.

valerianic acid and a volatile oil, containing a lerol, $C^6H^{10}O$ (see Hops, Oil of). The resinous illation still retains a considerable portion of d lime, yields valeraldehyde, $C^5H^{10}O$.

s, according to Payen, Chevallier, and Pelletan, dissolved portion consists almost wholly of resin, latter soluble in water, whereas the resin, which lin, is insoluble. This resin, when purified by ion by water, and drying, gives by analysis num- formula, $C^{54}H^{70}O^{11}$, together with a quantity of according as the resin has been more frequently by water.

yen, Chevallier, and Pelletan, and called by them to between 8·3 and 12·5 per cent. of the lupulin. alic acid, in the water in which lupulin has been is saturated with chalk, the liquid evaporated to ether, which dissolves a small quantity of resin. he malate of calcium by solution in alcohol, and s prepared is white or yellowish, or sometimes nt, sometimes opaque. It has no odour, unless

Digitized by Google

when strongly heated, in which case it exhales the odour of hops (perhaps in consequence of retaining a small portion of essential oil); it possesses the characteristic taste of hops. It has not been analysed. It is soluble in alcohol, but nearly insoluble in ether. By dry distillation it yields a considerable quantity of empyreumatic oil, but no ammoniacal products.

The tannin or astringent principle of the hop was for a long time regarded as identical with gallotannic acid, and as capable of conversion into gallic acid, and this change was supposed to account for the fact that old hops are not capable of clarifying beer. But, according to A. Wagner, gallic acid cannot be detected, even in very old hops quite unfit for making beer. He regards the tannic acid of hops as identical with morintannic acid, and finds that it amounts to between 3·2 and 5·7 per cent. of the hops.

According to Payen and Chevallier, the active principles of the hop do not reside exclusively in the lupulin, as was formerly supposed; they found, indeed, that hop-cones completely freed from lupulin, still yielded about 26 per cent. of substances soluble in alcohol.

To discover whether hops have been sulphured, Wagner treats them with granulated zinc, water, and pure hydrochloric acid. Any sulphurous acid that may be present is then reduced by the nascent hydrogen, and the liberated sulphur uniting with the hydrogen, forms sulphydric acid, which, if passed into a solution of nitroprussiate of sodium, generates a deep purple colour (ii. 257). This reaction will detect extremely small quantities of sulphurous acid; larger quantities may be detected by the odour, by the precipitation of iodine from a solution of iodate of potassium, and by various other reactions.

The ashes of hop-cones yield by analysis the following results:—

The hops analysed by Watts were grown on a heavy clay-soil near Hawkhurst in Kent. The crop was rather above the average, viz. 12 cwt. to the acre. By comparing this amount with the analysis of the ash, it is found that the hops grown on an acre of ground extracted from the soil 87 pounds of mineral constituents, including 12 to 13 oz. of phosphoric acid (P^2O^5), 17 lbs. potash (K^2O), and 15 lbs. 10 oz. of silica. This is sufficient to account for the well-known exhaustive effect of this plant on the soil. (For the statistics of the growth of hops in this country, see *Ure's Dictionary of Arts*, &c., ii. 460.)

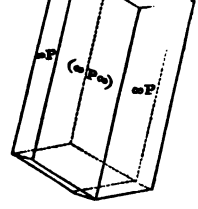
having the odour of thyme, and consisting, according to R. Wagner (Dingl. pol. J. cxxviii. 217), of a hydrocarbon isomeric with oil of turpentine, and an oxygenated oil, apparently identical with valerol, $C^{8}H^{16}O$, and convertible by oxidation into valerianic acid, and perhaps also some of its higher homologues: hence the odour of old cheese, which hops acquire by keeping. The non-oxygenated oil is not altered by contact with the air, but the greater part of it is gradually dissipated by volatilisation.

According to Personne (J. Pharm. [3] xxvi. 2419; xxvii. 22), lupulin distilled with water, yields valerianic acid and an essential oil lighter than water, colourless and neutral after rectification, but becoming acid and resinous after some time. It begins to boil at 140° C., but the boiling point gradually rises to 300°. The portions distilling between 150° and 160°, and those which distil at about 300°, appear to have the same composition, viz. $C^{11}H^{18}O$. Both these portions of the distillate turn the plane of polarisation to the right; remain fluid at − 17°; dissolve without red colour in sulphuric acid; are converted by nitric acid into valerianic acid and a resinous substance; and when let fall by drops on melting caustic potash, yield a hydrocarbon, $C^{10}H^{16}$, and valerate of potassium. Hence, Personne regards the volatile oil of lupulin as analogous to essence of valerian, which, according to Gerhardt, consists of borneene, $C^{10}H^{16}$ (i. 626), and valerol, $C^{5}H^{10}O$. The hydrocarbon from oil of hops is not, however, identical with borneene, inasmuch as it cannot be converted into borneol.

HORDEIN. Barley-starch obtained by kneading barley-meal in water, and leaving the liquid to settle, does not dissolve completely when warmed with acidulated water, but leaves a pulverulent substance, to which Proust gave the name *hordein*. It appears, however, to be, not a definite substance, but a mixture of starch, cellular tissue, and an azotised body.



HORDEUM VULGARE. *Barley.*—The composition of the grain of barley, as determined by various observers, has been already given in the article Cereals (i. 825); also the composition of the ash of the grain, and of the straw and chaff, as determined by Way and Ogston, showing the limits between which the amounts of each constituent was found to vary. The following table (p. 168) contains a more detailed statement of the results of these ash-analyses.

HORN. See Horny Tissue (p. 170).

HORNBLENDE. *Amphibole.*—A mineral which plays an important part in the composition of rocks of the primitive and transition periods. Hornblende-rock and hornblende-slate consist almost entirely of it, and, in diorite (greenstone), syenite, hornblende-gneiss, &c., it enters as an essential constituent.

Hornblende forms prismatic crystals belonging to the monoclinic system. Ratio of axes, $a : b : c$, = 1·837 : 1 : 0·5401. Inclination of the clinodiagonal (b) to the principal axis (c) = 75·10°. The angle $\infty P : \infty P$ = 55° 30′; $+P : +P$ in the clinodiagonal principal section = 148° 30′; $oP : \infty P$ = 76° 59′. Ordinary combination $\infty P . [\infty P\infty] . +P . oP$. (*Fig. 556a.*) Twins with face of composition parallel to $\infty P\infty$, as in the figure. Cleavage perfect, parallel to ∞P. It is also found imperfectly crystallised; fibrous or columnar, coarse or fine, with fibres often like flax; sometimes lamellar, also granular, coarse or fine, and usually strongly coherent; sometimes friable. Hardness 5 to 6. Specific gravity 2·9 to 3·4. Lustre vitreous to pearly on cleavage-faces; fibrous varieties often silky. Colour varying from black to white, through various shades of green, inclining to blackish-green; common hornblende, which contains much iron, is nearly black. Streak uncoloured or paler than the mineral. Sometimes nearly transparent, usually translucent to opaque. Fracture subconchoïdal, uneven.

Fig. 556a.

The chemical composition of hornblende was formerly represented, in accordance with the results of older analyses, by the general formula $5M^{2}O.6SiO^{2}$ (or $4MO.3SiO^{2}$); but Rammelsberg (*Mineralchemie*, pp. 426, 494,) has shown, by comparison of the more recent analyses by himself and others, that all hornblendes are metasilicates, of the general formula $M^{2}O.SiO^{2}$ or $M^{2}SiO^{3}$. The metals included under the general symbol M are calcium, magnesium, iron and sodium, sometimes also manganese and potassium. These metals, replacing one another isomorphously, give rise to a great number of substances differing considerably in composition as well as in colour and other physical properties. A further variation is caused by the presence in many varieties of alumina, which enters, not in place of the protoxides $M^{2}O$, for the amount of the latter is not found to be in inverse proportion to that of the alumina, but in place of a certain portion of the silica, and in such proportion, according to Bonsdorff, that 1 at. SiO^{2} may be regarded as isomorphously replaced by 1 at. $Al^{2}O^{3}$ ($2SiO^{2}$ by $3Al^{2}O^{3}$), but according

The results of these analyses show that, in barley as in other cereals, the amount of ash is but little influenced by the nature of the soil, but is for the most part greatest in plants grown on clay soils. The amount of ash in the straw and chaff varies between wider limits than that of the grain; the latter varies as much in plants growing on the same as in those growing on different soils. The composition of the ash of barley-grain does not differ essentially from that of wheat (*q. v.*) in any respect excepting in containing a larger amount of silica.

d. Cummingtonite is a rose-red granular hornblende from Cummington, Mass chusetts, of specific gravity 3·42, and consisting of manganous silicate, $Mn''SiO^3$.

e. Arfvedsonite.—This is a black mineral found in Greenland, accompanying eud lyte. It was formerly regarded as a variety of hornblende, with which indeed it isomorphous; but, according to Rammelsberg, it is a distinct species, whose formula $2(M^2O.SiO^2) + Fe^2O^3.3SiO^2$, or $\frac{M^4}{(Fe^2)^{vi}}\Big\}Si^2O^{15}$. Rammelsberg's analysis gives 51·22 p cent. SiO^2, 23·75 Fe^2O^3, 7·80 FeO, 1·12 MnO, 2·08 CaO, 0·90 MgO, 10·58 Na^2O, 0· K^2O, 0·16 water, and a trace of alumina.

1—5. Rammelsberg (*Mineralchemie*, p. 490).—6. v. Waltershausen (*Vulkanische Gesteine*)

The minerals included under this head are mixtures of the isomorphous compound $M^2O.SiO^2$, $Fe^2O^3.3SiO^2$ and $3MO.2Al^2O^3$. (Rammelsberg.)

Common Hornblende.—This name is applied to the dark green and black alumino varieties, whether in crystals or massive. Specific gravity 3·1 to 3·4. The name allud to its toughness.—*Carinthin* is an aluminous and ferruginous hornblende from Cari thia. Specific gravity 3·127.

Uralite, from the Ural, has the cleavage structure and composition of hornblend but the external form of augite, and is regarded as a pseudomorph. The two speci are variously mingled in different specimens, showing the change in different stages progress.

Diastatite is a hornblende from Wermland in Sweden, differing, according to Brei haupt, from common hornblende, by a degree in the angle of the prism. *Pargasi* includes crystallised varieties (crystals usually thick and stout); of high lustre, ar rather dark shades of green. It is also granular.

Fine specimens of the dark-coloured hornblendes occur at Aussig and Treplitz Bohemia; Tunaberg in Sweden, and Pargas in Finland. In Corsica there is found variety of hornblende (*Verde di Corsica duro*) which admits of a high polish.

Altered forms of Hornblende.—Alterations of hornblende are mostly like those augite. Varieties often occur, containing water of hydration, especially asbestiform anthophyllite varieties. The ferruginous change by oxidation is common, and a varieties are exposed to alteration from infiltrating waters, holding carbonates, sil cates, &c., in solution, thus giving rise to magnesian, ferruginous, magnesio-ferruginou (chlorite), alkaline, or aluminous forms. Talc, steatite, serpentine, chlorite, mic pinite, chabasite, limonite, magnetite, occur as hornblende pseudomorphs.

HORNBLENDE-ROCK is a rock consisting either wholly of hornblende or that mineral mixed with quartz, and occasionally containing mica, iron pyrite magnetic iron ore, and garnet. *Hornblende-slate* is a slaty variety of hornblend rock. These rocks belong to the oldest formations; they seldom form extended bed occurring more generally in masses subordinate to granite, gneiss, &c.

HORN-LEAD. *Cerasine.* Native *chlorocarbonate of lead*, $PbCl^2.PbCO^3$, called from its external resemblance to horn.

HORN-QUICKSILVER. Native sub-chloride of mercury. (See Mercury.)

HORN-SILVER. Native chloride of silver. (See Silver.)

HORNSTONE. A variety of quartz resembling flint, but more brittle, and wit a more splintery fracture. It is often called *Chert*. It is often found as a petrifactio on wood, and is used for making mortars and various other articles.

HORNY TISSUE. *Epidermose.*—The epidermis of animals, hair, wool, sil feathers, nails, claws, hoofs, horn, scales, &c., are composed, for the most part, of substance containing less carbon, but more nitrogen and sulphur than the albuminoïd The epithelium which coats the internal cavities of the animal body, is also similarl constituted.

The substance, called horny tissue or epidermose, which forms the basis of all thes structures, is obtained, though very far from pure, by exhausting the parts containin it with boiling alcohol and ether, after they have been comminuted as much a possible. This treatment removes the fatty matters, together with the greater part

Digitized by Google

the salts and other foreign matters, but it does not ensure the perfect homogeneity of the undissolved residue. It is known, indeed, that the horny tissues are composed of a number of superposed layers, cell-walls and nuclei, which are perhaps not all of the same nature, but yet cannot be separated by the solvents above mentioned.

The substance thus obtained from the various horny tissues, has been analysed by Mulder, Scherer, Frémy and several other chemists, the results of whose analyses, though not agreeing very closely, still show that the substance forming the basis of these several tissues has, in all probability, the same chemical composition.

The proportion of ash is about 1 per cent.

Horny tissue melts when heated, and burns with a bright flame, exhaling a peculiar odour.

When exposed to the action of boiling water in a Papin's digester, it gradually dissolves, yielding an extract, which does not gelatinise on cooling. By simple maceration in water, cold or warm, the horny tissues are gradually loosened, and exhibit a cellular structure more or less distinct.

Caustic potash easily dissolves horny tissue, eliminating ammonia, especially with aid of heat, and forming a yellow solution, which, when treated with acids, gives off sulphydric acid and yields a white precipitate. When fused with *hydrate of potassium* it gives off hydrogen, and forms acetic, butyric, and valerianic acids, also leucine, tyrosine, &c. Strong solutions of caustic potash or soda are the best reagents for bringing out the cellular structure of the different horny tissues, epidermis, nails, horn, &c.

Strong *sulphuric acid* causes horny tissue to swell up, and partly dissolves it when heated. The solution diluted with water becomes turbid when neutralised with an alkali, or mixed with ferrocyanide of potassium. Prolonged ebullition with dilute sulphuric acid yields tyrosine, leucine, ammonia, &c.

Nitric acid, especially if hot, colours horny tissue yellow, and ultimately dissolves it; on addition of ammonia, the yellow solution acquires a darker colour, and finally assumes an orange tint. According to v. Laer, xanthoproteic acid is formed in the first instance, then saccharic, and finally oxalic acid.

Fuming *hydrochloric acid* produces with horny tissue the same blue or violet coloration as with albuminous substances, and gradually dissolves the tissue on boiling. According to v. Laer, hair immersed even in cold concentrated hydrochloric acid dissolves in the course of some weeks.

Acetic acid does not dissolve horny tissue, but only causes it to swell up.

When *chlorine* is passed into water containing in suspension horny tissue (prepared from hair), the tissue undergoes no change in external appearance, but after drying it is harsh to the touch, and dissolves completely in ammonia, with evolution of nitrogen.

HORSE-CHESTNUT. *Aesculus Hippocastanum.*—The bark of this tree contains two fluorescent substances, æsculin (i. 60) and fraxin or paviin (ii. 708). Pelletier and Caventou found in it a greenish fat oil, a red-brown resin, a bitter yellow substance, a peculiar red substance, tannin, and woody fibre.

The fully developed leaves contain quercitrin, which is also found in the ripe

seeds, but not in the undeveloped leaves, or in the coatings of the buds, or in the bark of the stem and branches; the leaves which fall in autumn contain only traces of it. (Rochleder, Wien. Akad. Ber. xxxi. 565.)

The seeds contain, according to Tipp (Vierteljahrschr. pr. Pharm. iii. 19), starch (about 14 per cent.), mucilage, gum, a non-drying oil, saponin, a tannic acid which turns iron-salts green, phosphoric acid, and calcium-salts. Frémy found in the seeds, saponin, a yellow colouring matter [? quercitrin] and a crystallisable bitter substance. Attempts have been made at various times to render the starch of horse-chestnut seeds fit for food by freeing it from the bitter substance by means of a weak alkaline ley. According to Flandin (Compt. rend. xxvii. 391) this is best effected by kneading the peeled and bruised seeds with water containing from $\frac{1}{100}$ to $\frac{1}{50}$ of their weight of carbonate of soda, and then washing them; perfectly white starch then separates, which may be used as an addition to wheat-flour. According to Belloc, the same result may be obtained by the use of pure water. But according to Flandin, the alkali is required to remove an acrid substance and an acid resin, as well as the bitter principle. (Compt. rend. xxviii. 83, 138.)

The cotyledons of horse-chestnut seeds have lately been examined by Rochleder (Wien. Akad. Ber. xlv.; Rép. Chim. pure, 1863, p. 219), who finds, in the alcoholic extract, a bitter substance, argyrescin, an amorphous yellow colouring matter, and a substance which he calls aphrodescin, formerly regarded by Frémy as saponin. These substances are extracted by successive treatment with alcohol, acetate of lead, water, and ether.

Argyrescin, $C^{54}H^{86}O^{24}$, is soluble in water and in alcohol, and is precipitated by ether from its solution in absolute alcohol. When the aqueous solution is evaporated, it remains in the form of a gummy mass. From its solution in weak alcohol, it separates on evaporation in microscopic crystals, having a silvery lustre. The crystals have the composition $2C^{54}H^{86}O^{24}.H^2O$. It dissolves in strong sulphuric acid, forming a solution which turns red when mixed with water. It is fusible, and burns with a very smoky flame.

Argyrescin is resolved by *acids* into argyrescetin and glucose:

$$C^{54}H^{86}O^{24} = C^{42}H^{62}O^{12} + 2C^6H^{12}O^6;$$

and by *alkalis* into æscinic acid, $C^{46}H^{80}O^{22}$, and propionic acid:

$$C^{54}H^{86}O^{24} + 3H^2O = C^{46}H^{80}O^{22} + 2C^3H^6O^2.$$

With alkalis, however, an intermediate product is sometimes obtained, namely, an acid whose barium-salt has the composition $C^{51}H^{82}Ba^2O^{24}$, thus:

$$C^{54}H^{86}O^{24} + 2H^2O = C^{51}H^{84}O^{24} + C^3H^6O^2.$$

This new acid likewise exists, ready-formed, in the cotyledons.

Aphrodescin, $C^{42}H^{64}O^{22}$, is soluble in water, and is precipitated from the hot solution by hydrochloric acid in bulky flocks. It is distinguished from saponin by its solubility in alcohol, and by its reaction with alkalis, which is similar to that of argyrescin, excepting that it yields butyric instead of propionic acid, thus:

$$C^{42}H^{64}O^{22} + 2H^2O = C^{40}H^{60}O^{22} + C^4H^8O^2.$$

Æscinic acid, $C^{46}H^{80}O^{22}$, is obtained by precipitation from its salts, as a gelatinous mass, becoming pulverulent when dry. When boiled with a quantity of alcohol not sufficient to dissolve it completely, it becomes partly crystalline, but does not alter in composition. By drying at 130° in a current of carbonic anhydride, it undergoes a decomposition, which Rochleder represents by the improbable equation $C^{184}H^{320}O^{98} = C^{92}H^{160}O^{46}$ (æscinic acid) + $C^{92}H^{160}O^{52}$.

Æscinate of potassium, $C^{46}H^{79}KO^{22}$, is crystallisable.—The *barium*-salt has the composition $C^{46}H^{78}Ba^2O^{22}$.—The *lead*-salt contains a still larger proportion of base.

Argyrescin, aphrodescin, and æscinic acid heated with hydrochloric acid, are resolved into sugar and a new substance, telescin $C^{26}H^{42}O^{14}$, or a product containing $C^{42}H^{70}O^{16}$. When these decompositions take place in alcoholic solutions, the products formed are not constant, because the telescin may then be further resolved into mannitan (?) and a compound isomeric with quinovic acid.

Æscinic acid, or rather telescin, dissolved in alcohol, mixed with hydrochloric acid, and boiled till a red colour is produced, undergoes a final decomposition, yielding a solution from which water throws down flocks of æscigenin, $C^{24}H^{38}O^4$, isomeric with choloïdic and with quinovic acid. This substance is soluble in sulphuric acid, and on adding sugar to the solution, a red colour is produced similar to that exhibited by the biliary acids when similarly treated.

The action of hydrochloric acid on an alcoholic solution of telescin or æscinic acid sometimes also yields an intermediate product $C^{26}H^{42}O^5$, which is isomeric with

quinovin, and may be regarded as a compound of æscigenin with 2 at. propionic acid:

$$C^{36}H^{56}O^{8} = C^{32}H^{50}O^{4} + 2C^{3}H^{4}O^{2}.$$

This view of its composition is supported by the formation of a compound, $C^{38}H^{44}O^{7}$ [?$C^{38}H^{46}O^{8}$], containing the elements of æscigenin and acetic acid, by the action of chloride of acetyl on æscigenin.

Rochleder considers it probable that æscigenin or its compounds may exist in other plants, and that cyclameïn and digitaliretin may belong to this group of compounds.

The ash of the different parts of the horse-chestnut tree has been analysed by E. Wolff (J. pr. Chem. xliv. 385; Jahresber. 1847–8, p. 1078), for the purpose of determining how the proportion of the different mineral constituents are modified in passing from one organ to another, and how these constituents are distributed throughout the several organs. To eliminate any local character from the results, the organs subjected to examination were selected from trees growing on two very different soils; one a stony porphyritic soil, the other a moist forest soil often overflowed, very rich in vegetable mould, and much more favourable to the growth of the trees than the former.

The mineral constituents were extracted by first charring the substance in a muffle heated not quite to redness, and exhausting the charcoal, first with water, then with dilute hydrochloric acid, drying the carbonaceous residue, and incinerating it completely in the muffle. The ash was then likewise exhausted with hydrochloric acid, and the united hydrochloric extracts, the aqueous extract, and the insoluble residue, were separately analysed. The results are given in the table on page 173.

The ash of the wood, bark and leaves of the horse-chestnut has also been analysed by E. Staffel (Ann. Ch. Pharm. lxxvi. 379; Jahresber. 1850, p. 661), chiefly with the view of determining whether the amount of the several inorganic constituents in the plant and its different organs varies with the season of the year. The method of analysis was similar to that adopted by Wolff, excepting that the charcoal was exhausted with water alone.

HORSE-FLESH ORE. A term applied by the Cornish miners to certain varieties of *purple copper*.

HOUGHITE. A hydrated aluminate of magnesium, occurring, as the material of pseudomorphous spinel, near Oxbow, and in Rossie, near Somerville, St. Lawrence county, New York. The crystals are in all conditions, from the pure spinel to octahedrons with rounded edges and pitted or irregular surfaces; it also occurs in flattened nodules. It is perhaps identical with *Völknerite* (*q. v.*). (Dana, ii. 135.)

HOVITE. A mixture of collyrite (i. 1084) with a hydrated carbonate of aluminium and calcium, found in the Upper chalk, in the neighbourhood of Hove, near Brighton. It is very soft and friable, having an earthy fracture and low specific gravity. (J. H. and G. Gladstone, Phil. Mag. [4] xxiii. 461; Jahresber. 1862, p. 743.)

* With a trace of manganic oxide.

Digitized by Google

HOWARDITE. A meteoric mineral, described by C. U. Shepard. (Sill. Am. J. [2] vi. 402.)

HUANOKINE. $C^{20}H^{24}N^2O$.—An alkaloïd, isomeric, or perhaps identical, with cinchonine; obtained from *China de Huanoco plana*, a cinchona-bark found in the Huanoco forests, north of Lima (A. Erdmann, Ann. Ch. Pharm. c. 341). The bark is repeatedly exhausted with water containing hydrochloric acid, and the base, precipitated by caustic soda, is purified by repeated solution in acid, and reprecipitation, till it becomes white, and finally by crystallisation from alcohol.

Huanokine crystallises in small colourless prisms, very similar in form to cinchonine. According to H. Hahn (Jahresber. 1858, p. 372), they are monoclinic prisms, exhibiting the faces ∞P . $\infty P\infty$. oP. Angle $\infty P : \infty P$ in the clinodiagonal principal section = 71°; $oP : \infty P\infty$ = 110°. Cleavable parallel to oP; less distinctly parallel to $\infty P\infty$. It is tasteless; but has a slight alkaline reaction, stronger in the alcoholic solution, which is also slightly bitter. It melts without decomposition, and solidifies in the crystalline form on cooling: at a stronger heat it sublimes. It is nearly insoluble in water, dissolves in 400 pts. alcohol of 80 per cent. at 17°; and in 110 pts. at the boiling heat; in 600 pts. ether at 17°; and in 470 pts. at the boiling heat. It is said to be a strong febrifuge.

The salts of huanokine are precipitated white by alkalis and alkaline carbonates, yellowish white by tincture of galls, white by mercuric chloride, yellow by chloride of gold.

The *sulphate* is nearly insoluble in water; but dissolves easily in excess of acid; the solution is not fluorescent.—The *hydrochlorate* is very soluble, and crystallises in large colourless prisms having an extremely bitter taste; not fluorescent. According to Hahn (*loc. cit.*) the crystals are rhombic prisms, with the faces $\infty P\infty$. $\breve{P}\infty$. P. Angle $\infty P : \infty P$ = 80°.— The *chloroplatinate* also forms rhombic crystals, ∞P . $\infty \breve{P}\infty$. P. Angle $\infty P : \infty P$ = 75°; angle between the macrodiagonal terminal edges and the principal axis = 132°.— The *tartrate* forms hemihedral rhombic crystals, ∞P . $\infty \breve{P}n$. oP . $\frac{P}{2}$. Angle $\infty P : \infty P$. = 138°; $\frac{P}{2} : \frac{P}{2}$ = 70°. (Hahn.)

According to De Vry (J. Pharm. [3] xxxii. 328), huanokine is identical with cinchonine, the differences observed by Erdmann between it and cinchonine having been probably due to admixture of quinidine or cinchonidine. He found that hydriodate of cinchonine agreed perfectly, in external character and in its relations to polarised light, with the hydriodate obtained from huanokine prepared by Erdmann himself.

HUDSONITE. A black mineral from Cornwall, Orange County, New York, near the Hudson River. Specific gravity 3·43 to 3·5. It cleaves like Hedenbergite, and is regarded by Dana as a variety of augite, having a considerable portion of the silica replaced by alumina. The composition is, however, more like that of hornblende. Smith and Brush (Sill Am. J. [2] xvi. 369) found in it:—

SiO^2	Al^2O^3	FeO	MnO	CaO	MgO	K^2O	Na^2O	Loss by ignition.
38·94	10·41	30·48	0·60	10·36	3·00	2·48	1·66	1·95 = 99·88

Kenngott found that a mineral from Monroe, designated as Hudsonite, was really a hornblende. (*Rammelsberg's Mineralchemie*, p. 996.)

HUMBOLDTILITE. Syn. with Melilite.

HUMBOLDTINE. Syn. with Oxalite.

HUMBOLDTITE. Syn. with Datholite.

HUMIC ACID. See Ulmic acid.

HUMITE. See Chondrodite (i. 930).

HUMOPIC ACID. $C^{22}H^{25}O^7$ (?) (Wöhler, Ann. Ch. Pharm. l. 21).—An acid produced, with evolution of ammonia, by heating narcotine to about 220°.

$$C^{22}H^{23}NO^7 = C^{22}H^{25}O^7 + NH^3 [?]$$

It is purified by dissolving it in potash, precipitating with hydrochloric acid, re-dissolving in alcohol, and precipitating by water. It is an amorphous, dark-brown substance, insoluble in water and in dilute acids, but dissolves in alcohol with yellowish-red, and in alkalis with yellow colour, the latter solution forming brown gelatinous precipitates with barium- and lead-salts.

Wöhler's analysis of this acid gave 63·0 and 64·5 per cent. carbon, 5·3 and 5·0 hydrogen; whence he suggested the formulæ, $C^{44}H^{22}O^{27}$ and $C^{40}H^{19}O^{14}$. The formula above given (which requires 66·7 per cent. carbon and 5·3 hydrogen) is based upon the formula of narcotine recently established by Matthiessen and Foster (*Gmelin's Handbook*, v. 138). It is probable, however, that the acid has not been obtained pure,

Digitized by Google

and that the decomposition of narcotine by heat may be more complicated than that which is represented by the preceding equation.

HUMOURS OF THE EYE. See Eye (ii. 654).

HUMUS, or *Vegetable Mould*, is the product of the decay of vegetable matter. The fallen leaves, and all the parts of plants which are returned to the soil, either during the life of the plant or after its death, undergo peculiar alterations, the result of which is to transform them into a mass of compounds whose nature has not been exactly ascertained, but which are known to contain a large proportion of carbon. This decay is promoted by the action of air, by moisture, and by a certain degree of heat. It takes place most quickly in those constituents of the plant which are soluble in water, some of the insoluble matters, such as resins and fats, resisting decomposition for a long time, and remaining almost in their original state, so that they may be extracted from the humus by alcohol or ether. The decomposition is also greatly accelerated by the presence of putrifying nitrogenous matters; and this is doubtless one cause of the beneficial effect of animal manure.

Vegetable mould is in a continual state of slow combustion, whereby the organic compounds which it contains are gradually resolved into carbonic acid, water, and ammonia, which, as they are formed, are taken up by the roots and plants: hence the effect of vegetable mould in promoting the growth of plants, and partly also the advantage gained by frequently turning up and pulverising the soil, whereby the access of air and the decomposition of the organic matter are facilitated.

HUNTERITE. The name applied by S. Haughton (Phil. Mag. [4] xvii. 18; Jahresber. 1859. p. 289) to a hydrated silicate of aluminium, having a fatty lustre and the aspect of felspar, found in a coarsely crystalline granite in the neighbourhood of Nágpur in Central India. Specific gravity = 2·319. According to Haughton's analysis, it contains 65·93 per cent. SiO^2, 20·97 Al^2O^3, 0·30 CaO, 0·45 MgO and 11·61 water (= 99·26). This is very nearly the composition of cimolite (i. 984), with which also the mineral agrees nearly in lustre and specific gravity: hence Dana (Sill. Am. J. [2] xxviii. 133) regards it as identical with cimolite.

HUREAULITE. A phosphate of iron and manganese from Hureault, near Limoges, where it occurs in small veins in the granite. It forms translucent crystals belonging to the monoclinic system, having a yellowish- or reddish-brown colour and vitreous lustre. Specific gravity = 2·27. Somewhat softer than felspar; contains, according to the mean of Damour's analyses (Ann. Min. [5] v.), 38·00 per cent. P^2O^5, 41·67 MnO, 7·86 FeO, 11·98 water, and 0·38 quartz &c.; whence the formula $\left.\begin{matrix}\frac{5}{6}MnO\\ \frac{1}{6}FeO\end{matrix}\right\}^3.2P^2O^5 + 5H^2O$; or it may be a double salt consisting of a pyro- and ortho-phosphate, of the form $M^4P^2O^7.2M^3PO^4.5H^2O$. (*Rammelsberg's Mineralchemie*, p. 330.)

HURIN. An acrid crystalline substance obtained from the juice of *Hura crepitans*. (Boussingault and Rivero, Ann. Ch. Phys. [2] xxviii. 430.)

HURONITE. A mineral from Lake Huron, containing 45·80 SiO^2, 33·92 Al^2O^3, 8·04 CaO, 4·32 FeO, 1·72 MgO and 4·16 water. It forms imperfectly laminated masses, having a light greenish yellow colour and waxy lustre, translucent on the edges. (Handw. d. Chem. iii. 942.)

HVERSALT. Native iron-alum from Iceland. (See Sulphates.)

HYACINTH. See Zircon.

HYÆNANCHE GLOBOSA. (Lamb).—A euphorbiaceous plant, the pericarp of which contains a very acrid poisonous substance, resembling strychnine and the allied poisons in its action. The poisonous substance is uncrystallisable, easily soluble in water and in alcohol; it has neither basic nor acid properties, but cannot be classed among the resins, on account of its solubility in water. The husk of the fruit contains 9·40 per cent. water, 5·36 gypsum, lime, potash, and chlorine; 2·52 wax and chlorophyll; 9·64 tannic acid; 5·64 resin; 15·15 starch, gum, and sugar; 3·99 varnish-like substance, soluble in water and in alcohol; 36·00 cellulose; and lastly, oxalic acid, and substances which can be extracted by strong hydrochloric acid and potash-ley. The seeds give up to ether, 41·06 per cent. of a green-yellow fat oil, then to alcohol 24·13 per cent. of a nearly black, brittle resin, resembling kino; they contain 10·7 per cent. of inorganic matters. (J. B. Henkel, Arch. Pharm. [2] xciv. 16; Jahresber. 1858, p. 532.)

HYALITE. See Opal.

HYALOMELANE. Syn. with Trachylyte.

HYALOPHANE. A barytic felspar resembling adularia, discovered by Sartorius v. Waltershausen (Pogg. Ann. xciv. 134; c. 547) in the dolomite of the Binnenthal in the Valais. It is transparent and colourless when pure, but often milk-white from admixture of sulphate of barium. Hardness between 6 and 7. Specific

Digitized by Google

gravity = 2·77 to 2·83. It forms monoclinic crystals resembling those of adularia, ∞P . oP . $+P\infty$, often with ($\infty P\infty$). Angle ∞P: ($\infty P\infty$) = 120° 36′; oP : ∞P = 112° 0′; oP : $+P\infty$ = 130° 36′. Cleavage perfect parallel to $P\infty$ (Waltershausen). The analysis of a perfect limpid specimen by Stockar-Escher (*Kenngott's Uebersicht*, 1856–57, p. 107) gave:

SiO^2	Al^2O^3	BaO	CaO	MgO	K^2O	Na^2O	H^2O
52·67	21·12	15·05	0·46	0·04	7·82	2·14	0·58 = 99·88;

whence the formula $\left.\begin{matrix}BaO\\K^2O\end{matrix}\right\}SiO^2 + Al^2O^3.3SiO^2 = \left.\begin{matrix}Ba^{\cdot}K^{\cdot}\\Al'''\end{matrix}\right\}Si^2O^6 = \left.\begin{matrix}\overset{\cdot\cdot}{Si^2}\\(Ba^{\cdot}K^{\cdot})'\\Al'''\end{matrix}\right\}O^8$;

which is similar to that of andesin (see FELSPAR, ii. 618). (*Rammelsberg's Mineralchemie*, p. 609.)

HYALOSIDERITE. A variety of chrysolite from the Kaiserstuhl mountain in the Breisgau, where it occurs in yellowish and brownish-red crystals. It contains 31·63 SiO^2, 32·40 MgO, 28·49 FeO, 0·48 Fe^2O^3, 2·21 Al^2O^3, 2·79 K^2O, and a trace of chromium. To bring it under the formula of chrysolite, $2M^2O.SiO^2$ or M^4SiO^4, it is necessary to suppose that part of the silica is isomorphously replaced by alumina.

HYELITE. See PALAGONITE.

HYDANTOIC ACID. $C^4H^8N^4O^4$ (?)—An acid produced by the action of potash on allantoïn. On supersaturating the solution with acetic acid, precipitating with acetate of lead, decomposing the lead-salt with sulphuretted hydrogen, and evaporating the filtered liquid, the acid is obtained as an uncrystallisable syrup, deliquescent and insoluble in alcohol. It probably contains the elements of allantoïn *plus* 1 at. water ($C^4H^6N^4O^3.H^2O$). (Schlieper.)

The name hydantoic acid is also applied by Baeyer to an acid formed from hydantoïn by addition of the elements of water: no description of it has yet been given.

HYDANTOÏN. $C^3H^4N^2O^2$. (A. Baeyer, Ann. Ch. Pharm. cxvii. 179.)—A compound belonging to the parabanic acid group, produced from allantoïn by the reducing action of hydriodic acid:

$$\underset{\text{Allantoïn.}}{C^4H^6N^4O^3} + 2HI = \underset{\text{Urea.}}{CH^4N^2O} + \underset{\text{Hydantoïn.}}{C^3H^4N^2O^2} + I^2.$$

Also, together with a small quantity of allanturic acid, by the action of hydriodic acid on alloxanic acid:

$$\underset{\text{Alloxanic acid.}}{C^4H^4N^2O^5} + 2HI = \underset{\text{Hydantoïn.}}{C^3H^4N^2O^2} + CO^2 + H^2O + I^2.$$

It crystallises with great facility in colourless crystals easily soluble in water; tastes slightly sweet, and grates a little between the teeth. It is converted by oxidation into allanturic acid:

$$\underset{\text{Hydantoïn.}}{C^3H^4N^2O^2} + O = \underset{\text{Allanturic acid.}}{C^3H^4N^2O^3}.$$

With water it forms Baeyer's hydantoïc acid.

HYDRACIDS. A term formerly applied to hydrochloric, hydrobromic, hydriodic, hydrofluoric, and hydrocyanic acids, to distinguish them from acids containing oxygen. The distinction is, however, no longer maintained, all acids being now regarded as salts of hydrogen. (See ACIDS.)

HYDRACRYLIC ACID. $C^{12}H^{22}O^{11}$.—An acid produced by the decomposition of iodopropionic acid, when a solution of a salt of that acid is heated to boiling:

$$4C^3H^5IO^2 + 3H^2O = C^{12}H^{22}O^{11} + 4HI.$$

It is most easily prepared by digesting iodopropionic acid with excess of silver-oxide, decomposing the resulting silver-salt with sulphydric acid, and evaporating the filtrate. Hydracrylic acid then remains in the form of a syrup, mixed with slender needles. It is tribasic; nearly all its salts are easily soluble in water, and many of them are decomposed by heat, with formation of acrylic acid:

$$\underset{\text{Hydracrylic acid.}}{C^{12}H^{22}O^{11}} = 4\underset{\text{Acrylic acid.}}{C^3H^4O^2} + 3H^2O.$$

The *cupric salt* is a blue-green varnish. The *lead-salt*, $C^{24}H^{20}(Pb'')^2O^{22}$, forms a white, crystalline, deliquescent mass, perfectly insoluble in alcohol, and decomposing when heated to between 150° and 200°. The *silver-salt*, $C^{12}H^{18}Ag^4O^{11}$, is a flocculent mass, becoming dark-coloured and amorphous when dry, easily soluble in water, sparingly in alcohol, insoluble in ether; decomposing below 100°. (Beilstein, Ann. Ch. Pharm. cxxii. 366.)

HYDRAMIDES. A group of tertiary diamides (i. 172), formed by the action

Digitized by Google

of ammonia on certain aldehydes, 2 at. of ammonia uniting with 3 at. of the aldehyde, and 3 at. water being eliminated, as shown by the equation—

$$\underset{\text{Bitter Almond Oil.}}{3C^7H^6O} + 2NH^3 = \underset{\text{Hydrobenzamide.}}{N^2(C^7H^6)^3} + 3H^2O$$

The following are the hydramides at present known:—

Furfuramide . . .	$C^{15}H^{12}N^2O^3$	$= N^2(C^5\ddot{H}^4O)^3$
Hydranisamide . . .	$C^{24}H^{24}N^2O^3$	$= N^2(C^9\ddot{H}^8O)^3$
Hydrobenzamide . . .	$C^{21}H^{18}N^2$	$= N^2(C^7\ddot{H}^6)^3$
Hydrocinnamide . . .	$C^{27}H^{24}N^2$	$= N^2(C^9\ddot{H}^8)^3$
Hydrosalicylamide . . .	$C^{21}H^{18}N^2O^3$	$= N^2(C^7\ddot{H}^6O)^3$
Hydrobromosalicylamide .	$C^{21}H^{15}Br^3N^2O^3$	$= N^2(C^7\ddot{H}^3BrO)^3$
Hydrochlorosalicylamide .	$C^{21}H^{15}Cl^3N^2O^3$	$= N^2(C^7\ddot{H}^3ClO)^3$

Glycosine, $N^2(C^{\prime\prime\prime\prime}H^2)^3$, from glyoxal (ii. 919), may also be regarded as a hydramide, or rather hydramine.

The aldehydes of the fatty acids (acetic aldehyde and its homologues) do not appear to yield compounds of this class.

The hydramides are crystalline solids, insoluble in water, soluble in alcohol, not volatile without decomposition, and not possessing alkaline properties; but when left in contact with strong caustic alkalis (Fownes), or when simply raised to a high temperature (Bertagnini), they are converted into isomeric compounds possessing strong basic properties, *e. g.* furfuramide into furfurine, hydrobenzamide into amarine. The difference of constitution between these bases and the corresponding hydramides is not precisely understood; but Borodine has shown that amarine contains a larger number of atoms of replaceable hydrogen than its isomer, hydrobenzamide. (See HYDROBENZAMIDE.)

Some hydramides, *e. g.* hydrobenzamide and hydrosalicylamide, are decomposed by acids, yielding ammonia and the corresponding aldehydes. By sulphydric acid they are converted into sulphuretted aldehydes (thialdides), *e. g.* furfuramide into thiofurfol:

$$\underset{\text{Furfuramide.}}{(C^5H^4O)^3N^2} + 3H^2S = 2NH^3 + \underset{\text{Thiofurfol.}}{3C^5H^4OS}.$$

HYDRANZOTIN. $C^2H^4N^2S^4$. *Disulphide of Sulphocarbammonium, Dihydrosulphuretted Sulphocyanogen* (Zeise, Ann. Ch. Pharm. xlviii. 95; Debus, *ibid.* lxxiii. 27).—When chlorine-water is added by small portions to a solution of sulphocarbamate of ammonium in 5 or 6 pts. of water, the liquid being well shaken, and care being taken to avoid an excess of chlorine, this body is produced, as a flocculent crystalline precipitate, which must be washed with cold water till the wash-water no longer reddens ferric salts, and dried in vacuo. It is also produced by heating an aqueous solution of sulphocarbamate of ammonium, first with a large excess of sulphuric or hydrochloric acid, then with a ferric salt.

Hydranzotin, when first prepared, is colourless, with a nacreous lustre, and inodorous; but after a while it gives off sulphuretted hydrogen. It is very sparingly soluble in *water*, dissolves without alteration in *alcohol*, and is dissolved by *ether* in very large quantity, but with some alteration, the solution reddening litmus. An alcoholic solution of *potash* dissolves a considerable portion of it, yielding a neutral liquid, which, when boiled, yields sulphide of potassium, sulphocyanate of potassium and sulphur.

The same transformation takes place on boiling the solution of the compound in absolute alcohol:

$$C^2H^4N^2S^4 = H^2S + 2CHNS + S.$$

The compound is not decomposed by trituration with oxide of lead, unless the mixture is heated. By *dry distillation* it yields sulphide of carbon, accompanied by a little sulphydric acid, and sulphydrate and sulphocarbonate of ammonium, leaving a small quantity of a black substance. It is not perceptibly decomposed by sulphuric or hydrochloric acid.

HYDRARGAMYL, HYDRARGETHYL, &c. See MERCURAMYL, MERCURETHYL, &c.

HYDRARGYLLITE. See GIBBSITE (ii. 838).

HYDRARGYRUM. Syn. with MERCURY.

HYDRASTINE. An alkaloïd discovered by J. D. Perrins (Pharm. J. Trans. [2] iii. 546) in the root of *Hydrastis Canadensis*, in which it exists to the amount of about

acid or alcoholic radicle: other examples of such hydrates (which may also be regarded as anhydrides, inasmuch as they are formed by dehydration of normal hydrates) will be found under ETHYLENE, HYDRATES of (ii. 576), GLYCERYL, HYDRATES of (ii. 894), GLYCEROTARTARIC ACIDS (ii. 893).

Metallic hydrates retain the elements of water with various degrees of force. Hydrate of copper parts with its water at a very moderate heat; hydrate of calcium, at a strong red heat; while the hydrates of potassium and sodium are not decomposed by the strongest heat that can be applied to them. Hydrated acids likewise exhibit various degrees of stability. Tribasic phosphoric acid, $P^2O^5.3H^2O$ or PH^3O^4, gives off part of its water at a red heat, being converted first into the dibasic acid, $P^2O^5.2H^2O$, and ultimately into the monobasic acid, $P^2O^5.H^2O$, which resists further decomposition. The hydrates of volatile acids exhibit remarkable relations to heat. Under given circumstances of pressure and temperatures, there is for each acid a certain proportion of water which forms a stable compound, a weaker acid under that pressure and temperature giving off water, and a stronger acid giving off acid, till the most stable compound remains behind (Roscoe, Chem. Soc. Qu. J. xiii. 146). See SULPHURIC ACID, NITRIC ACID, CHLORHYDRIC ACID, &c.

The hydrates of the stronger acids and bases may be formed by direct combination of the anhydrous base or acid (anhydride) with water, the combination being sometimes attended with great evolution of heat, as in the case of sulphuric acid, baryta, and lime. In other cases, the hydrate cannot be formed directly, and in others again the union takes place but slowly. Acetic anhydride may be left in contact with water for several days without dissolving in it; but on the application of heat, it gradually dissolves. Among organic acids, it is found that dibasic acids are formed by the direct union of the anhydride and water, and that the hydrate may be decomposed by heat: this is the case with succinic and tartaric acids; whereas the hydrates of monobasic acids, such as acetic acid, cannot be thus decomposed by heat alone. This difference is probably related to the fact, that the molecule of a dibasic acid, like succinic acid, $\left.\begin{matrix}(C^4H^4O^4)'' \\ H^2\end{matrix}\right\}O^2$, contains a sufficient number of atoms of basic hydrogen to form water; whereas the molecule of a monobasic acid, such as acetic acid, $\left.\begin{matrix}C^2H^3O \\ H\end{matrix}\right\}O$, does not.

The hydrates of lithium, sodium, potassium, barium, strontium, and thallium, are easily soluble in water, forming strongly alkaline solutions; hydrate of calcium is moderately soluble; the other metallic hydrates are insoluble or nearly so; those of magnesium, mercury, lead, and silver are, however, sparingly soluble. The hydrates of the more acid or chlorous radicles are all more or less soluble in water, with the exception of certain organic acids of high atomic weight, such as the higher members of the fatty acid series, palmitic, stearic, cerotic acid, &c.: these bodies dissolve readily in alcohol and in ether. Similar remarks apply to the alcoholic hydrates.

In many hydrated compounds, part or the whole of the oxygen and hydrogen appears actually to exist as water, as in bases, salts, &c., containing water of crystallisation: *e.g.* crystallised *hydrate of barium*, $Ba''H^2O^2.8H^2O$, *crystallised alum* $(SO^4)^2Al'''K.12H^2O$. Water can unite in this manner with salts and other bodies in the most various proportions, sometimes one molecule of the salt being united with several molecules of water, as in the instances above given, and sometimes, though less frequently, one molecule of water with two or more molecules of the salt; sometimes in more complex proportions, as in crystallised *nitrate of strontium*, $Sr''(NO^3)^2.5H^2O$.

Water thus united with a salt or other body is for the most part expelled at 100° C.: some salts, however, retain part of their water with greater tenacity than the rest; thus crystallised sulphate of zinc, $Zn''SO^4.7H^2O$, gives off 6 at. water at 100°, but retains the seventh atom till heated to 238°; sulphate of magnesium, $Mg''SO^4.7H^2O$, exhibits a similar deportment. Moreover, this last atom of water, which by its greater stability appears to be more intimately united with the salt than the rest, may be replaced by a molecule of another salt, as sulphate of potassium or ammonium:

Crystallised sulphate of zinc . . .	$Zn''SO^4.H^2O$ + 6 aq.
Sulphate of zinc and potassium . . .	$Zn''SO^4.K^2SO^4$ + 6 aq. or $Zn''K^2(SO^4)^2$ + 6 aq.

Water united with a salt in this manner is called by Graham *constitutional water*, to distinguish it from water of crystallisation. Liebig distinguishes these hydrated compounds, *e.g.* $Zn''SO^4.H^2O$, by the term *kalhydrates*.

HYDRAULIC LIMESTONE. See LIMESTONE.

HYDRIDES. This term is applied chiefly to the compounds of hydrogen with metals, alcohol-radicles, and organic acid-radicles, *e.g.* hydride of copper, Cu^2H^2; hydride of ethyl, $C^2H^5.H$; hydride of benzoyl, $C^7H^5O.H$.

Metallic Hydrides. A few only of these compounds are known. The most important are the gaseous hydrides of *arsenic* and *antimony*, AsH^3 and SbH^3 (i. 322. 371), formed on the ammonia type. *Phosphoretted hydrogen*, or *phosphamine*, PH^3, belongs to the same class. There is also a solid hydride of arsenic, supposed to have the composition AsH^1, produced when water is electrolysed by a strong current, with metallic arsenic for the negative pole. It is doubtful whether a hydride of *bismuth* exists, analogous to the gaseous arsenides of arsenic and antimony. Hydride of *copper*, Cu^2H^2, produced by the action of hypophosphorous acid on aqueous cupric sulphate, is remarkable for its reaction with hydrochloric acid, the products of which are cuprous chloride, Cu^2Cl^2, and free hydrogen (ii. 66). A hydride of *iron* has been obtained by Wanklyn and Carius (Ann. Ch. Pharm. cxx. 69) by acting on ferrous iodide with zinc-ethyl. It is a black metallic powder, which gives off hydrogen when immersed in water.

Hydrides of Alcohol-radicles.—1. Of the radicles C^nH^{2n+1}. These hydrides are the homologues of marsh-gas, or hydride of *methyl*, $CH^3.H$, the lowest term of the series. The hydrides of *ethyl*, *trityl*, and *tetryl* are gaseous at ordinary temperatures; the rest, up to $C^{15}H^{32}$, the highest yet obtained, are liquids of more or less disagreeable odour, burning with a slightly smoky flame, and regularly increasing in specific gravity, vapour-density, and boiling-point, as their atomic weights become greater. The highest terms of the series will doubtless be found to be solid waxes and paraffins.

Hydride of *methyl* (marsh-gas) is produced by the putrefaction and dry distillation of organic bodies, and by distilling acetic acid or acetone with excess of potash (i. 13). Hydride of *ethyl* is obtained by the decomposition of ethyl itself, which under certain circumstances splits up into this compound and ethylene (ii. 565):

$$2C^2H^5 = C^2H^5.H + C^2H^4;$$

also when iodide of ethyl is decomposed by zinc in presence of water:

$$2C^2H^5I + H^2O + Zn^2 = 2(C^2H^5.H) + Zn^2I^2O.$$

Hydride of *tetryl*, $C^4H^9.H$, is produced by heating tetrylic alcohol with chloride of zinc, and hydride of *amyl*, $C^5H^{11}.H$, together with several of its higher homologues, by similar treatment of amylic alcohol (p. 147).

Hydride of amyl and some of its homologues are also contained, together with other hydrocarbons, in the light oils resulting from the distillation of Boghead coal (Gr. Williams, Phil. Trans. 1857, p. 727; Jahresber. 1857, p. 437.—Chem. Soc. J. xv. 130), and of Wigan cannel coal (Schorlemmer, Chem. Soc. J. xv. 419): for the mode of separating them, see p. 146. Many of these alcoholic hydrides are also contained in American petroleum or earth-oil (which indeed appears to consist almost entirely of them), hydride of *hexyl*, C^6H^{14}, constituting the principal portion (Pelouze and Cahours, Ann. Ch. Pharm. cxxiv. 289; cxxvii. 196; cxxix. 87). They are separated by fractional distillation, and purified by successive treatment with sulphuric acid and carbonate of sodium, desiccation with anhydrous chloride of calcium, distillation over sodium, and final rectification. In this manner, Pelouze and Cahours have obtained twelve of these hydrides, included under the general formula C^nH^{2n+2}, from hydride

of tetryl, C^4H^9, boiling at a few degrees above 0°, to hydride of pentadecatyl, C
boiling between 255° and 260°. The oil also yields a quantity of liquid boiling
300°, and doubtless containing some of the higher terms of the same series. More
in boring for it, large quantities of gas escape, exhibiting the characters of marsh
hence it is probable that, in the great geological changes which have given rise t
separation of this remarkable liquid, the whole series of homologous alcohol-hyd
C^nH^{2n+2} has been produced, from marsh-gas up to the highest paraffins.

The preceding table (p. 181) exhibits the specific gravities and boiling-points o
alcoholic hydrides obtained from these several sources. The vapour-densities hav
been determined in all cases, and found to agree nearly with those calculated fro
respective formulæ for a condensation to 2 volumes. Wurtz's determinations
made on the hydrides obtained by the decomposition of amylic alcohol; Schorlem
on those from cannel-naphtha; those of Pelouze and Cahours, on the hydrides
American petroleum.

These alcoholic hydrides are very stable compounds. They are little, if at all,
upon by fuming *nitric acid*, strong *sulphuric acid*, or *bromine*; but *chlorine* co
them all into the corresponding alcoholic chlorides $C^nH^{2n+1}Cl$.

Each alcoholic hydride of the series $C^nH^{2n+1}.H$ (except hydride of meth
identical in composition with a radicle, simple or mixed, belonging to the same s
thus—

Hydride of Ethyl	$C^2H^5.H$	= Methyl	$CH^3.CH^3$
,, Trityl	$C^3H^7.H$	= Methyl-ethyl	$CH^3.C^2H^5$
,, Tetryl	$C^4H^9.H$	= Ethyl	$C^2H^5.C^2H^5$
,, Amyl	$C^5H^{11}.H$	= Ethyl-trityl	$C^2H^5.C^3H^7$
		= Methyl-tetryl	$CH^3.C^4H^9$

and generally:

$$C^{2m}H^{4m+1}.H = C^m H^{2m+1}.C^mH^{2m+1}$$

$$C^{2m+1}H^{4m+3}.H = C^mH^{2m+1}.C^{m+1}.H^{2m+3}$$

The question, therefore, arises: are the members of the two series, the al
radicles and their hydrides, identical or only isomeric? Soon after the isolation
alcohol-radicles by Frankland and Kolbe, in 1849, Laurent and Gerhardt pronou
the opinion that these compounds were the homologues of marsh-gas. This view
not been generally received as correct (see ALCOHOL-RADICLES i. 96); but rec
Schorlemmer (Chem. Soc. J. xv. 425) has endeavoured to solve the questi
examining the products obtained by the action of chlorine on the radicles and
isomeric hydrides. He finds that ethyl-amyl, $C^2H^5.C^5H^{11}$, treated with chlorine,
a chloride, $C^7H^{15}Cl$, agreeing in composition, as well as in boiling point and
physical properties, with that which is produced by the action of chlorine on hy
of heptyl (p. 144). From amyl, $C^{10}H^{22}$, Schorlemmer obtained, in like manner, a chl
$C^{10}H^{21}Cl$, boiling at about 200°, which he regards as identical with that which
obtained by the action of chlorine on hydride of decatyl, $C^{10}H^{21}.H$. From
results, Schorlemmer concludes that no chemical difference exists between the alc
hydrides and the radicles, at least among the higher members of the series.

2. *Hydrides of the Alcohol-radicles* C^nH^{2n-7}.—Two compounds of this serie
known, viz:—

Hydride of Phenyl (Benzene)	C^6H^6	=	$C^6H^5.H$
Hydride of Benzyl (Toluene)	C^7H^8	=	$C^7H^7.H$

Both these hydrides are contained in the light oils obtained by the distillati
coal. When treated with strong nitric acid, they yield substitution-products, in the fo
heavy oils, the formation of which affords the means of separating these hydroca
from those of other series with which they may be mixed (p. 146). The prepar
and properties of these hydrides have already been fully described (i. 542, 573).

The hydrides of alcohol-radicles of other series have not yet been obtained.

Hydrides of Acid-radicles: The aldehydes, referred to the hydrogen-type
constitute this class of compounds, *e.g.* acetic aldehyde, $C^2H^4O = C^2H^3O.H$; be
aldehyde (bitter-almond oil), $C^7H^6O = C^7H^5O.H$ (see ALDEHYDES, i. 110).

HYDROALOETIC ACID. An acid formed from aloetic or chrysammic ac
the action of water and stannous chloride. A dark violet powder is then prod
which at 120° contains, according to Mulder, $SnO^2.C^{14}H^4N^2O^{11}$. This stannic
treated with potash, gives off ammonia and assumes a blue-violet colour; and when h
with strong nitric acid, gives off nitrous fumes, turns red, and yields, first aloetic
then, after longer boiling, chrysammic acid (Mulder, Ann. Ch. Pharm. lxxii. 26

HYDROAPATITE. A hydrated phosphate of calcium, containing fluorine,

40·00 per cent. P^2O^5, 52·35 CaO, 3·36 F, and 5·30 water, together with 6·42 ferric phosphate, agreeing nearly with the formula $3Ca^3P^2O^8.CaF^2.3H^2O$. (Damour, Ann. Min. [5] x. 65; Jahresber. 1856, p. 874.)

HYDROBENZAMIDE. $C^{21}H^{18}N^2$. *Tribenzylene-diamide, Hydride of Azobenzoyl.* (Laurent, Ann. Ch. Phys. [2] lxii. 23; lxvi. 18; [3] i. 300.—Bertagnini, Ann. Ch. Pharm. lxxxviii. 127.)—This compound, which may be regarded as a tertiary diamide, $N^2(C^7H^6)^3$, in which the hydrogen is completely replaced by the diatomic radicle benzylene, is produced by the action of ammonia on hydride of benzoyl (bitter almond oil). When rectified bitter almond oil (boiling at 180°) is left in contact with aqueous ammonia for a few days, or for only six or eight hours if the liquid be previously heated to the boiling point of the ammoniacal solution, a crystalline mass is formed, which must be broken up, washed rapidly with ether to remove adhering oil, and then dissolved in boiling alcohol, which leaves undissolved a number of secondary products resulting from the action of the ammonia on hydrocyanic acid contained in the bitter almond oil. According to Ekman (Ann. Ch. Pharm. cxii. 151), hydrobenzamide may be obtained in fine crystals by mixing bitter almond oil with an equal volume of ether and strong aqueous ammonia, and leaving the mixture at rest.

Hydrobenzamide separates from its alcoholic solution in colourless octahedrons with a rhombic base, truncated on their longer lateral edges. Angles of the terminal edges, 130° and 122°; angles of the lateral edges, 84° 50′. It is insoluble in water, very soluble in alcohol and ether. The crystals are destitute of taste and odour, but the alcoholic solution has a taste of burnt almonds. The crystals melt at 110°, forming a thick oil, which has a sweet taste, and solidifies after a while to an opaque brown mass.

Decompositions.—1. Hydrobenzamide, when heated in the air, takes fire, and burns with a not unpleasant odour (Laurent).—2. Between 120° and 130° it changes in three or four hours into amarine (Bertagnini).—3. By *dry distillation*, it yields lophine and a strong-smelling volatile oil, leaving a small quantity of carbonaceous matter (Laurent).—4. When the alcoholic solution is continuously boiled, ammonia escapes, and on evaporating the alcohol, bitter almond oil remains (Laurent).—5. Boiled with aqueous *chromic acid*, it yields a large quantity of benzoic acid (Fownes, Phil. Trans. 1845, 263).—6. With *acids*, even at ordinary temperatures, it yields bitter almond oil and the ammonia-salt of the acid (Laurent, Fownes).—7. Boiled with *potash-ley*, it changes gradually and without perceptible decrease of weight, into amarine, only a faint odour of bitter almond oil being evolved (Fownes). Boiled with alcoholic potash, it gives off a small quantity of ammonia and bitter almond oil (Laurent).—8. When it is fused with *hydrate of potassium*, the mass becomes first light yellow, then dark yellow, and ultimately brown and black; and if slowly heated, gives off nothing but ammonia: if the heat be continued, there is given off, besides ammonia, a mixture of about 4 vol. hydrogen gas to 1 vol. carburetted hydrogen. The black residue contains carbonate and cyanide of potassium, benzostilbin, benzolone, and a small quantity of a yellow oil, which thickens and becomes viscid on exposure to the air; the mass, which has then become dark yellow, contains nothing but benzostilbin and a considerable quantity of the yellow oil (Rochleder, Ann. Ch. Pharm. lxi. 89).—9. Heated with *potassium*, it yields a red fusible mass and a small quantity of charcoal (Laurent).—10. When *sulphydric acid* is passed through the alcoholic solution, sulphide of benzylene is produced (Cahours).—11. A solution of hydrobenzamide in absolute alcohol mixed with a solution of *sulphurous anhydride* in absolute alcohol, deposits, after a while, a white precipitate of sulphite of benzoyl and ammonium, $C^7H^5(NH^4)SO^3$, and the remaining solution yields by distillation, first alcohol, then diethyl-benzylenic ether, $\left.\begin{matrix}(C^7H^6)''\\(C^2H^5)^2\end{matrix}\right\}O^2$ (R. Otto, Ann. Ch. Pharm. cxii. 305).—12. When hydrobenzamide is saturated with *hydrochloric acid gas*, a compound free from nitrogen slowly volatilises, whilst a non-volatile azotised compound remains behind, which is not altered by ether, but is dissolved by alcohol, with separation of sal-ammoniac. This compound (hydrochlorate of hydrobenzamide) is resolved by water into sal-ammoniac and hydride of benzoyl:

$$C^{21}H^{18}N^2.2HCl + 3H^2O = 2NH^4Cl + 3C^7H^6O,$$

and by absolute alcohol into sal-ammoniac and diethyl-benzylenic ether:

$$C^{21}H^{18}N^2.2HCl + 6C^2H^6O = 2NH^4Cl + 3\left[\left.\begin{matrix}(C^7H^6)''\\(C^2H^5)^2\end{matrix}\right\}O^2\right].$$

(Ekman, Ann. Ch. Pharm. cxii. 151; Jahresber. 1859, p. 317.—Lieke, ibid. 318).

Hydrochlorate of hydrobenzamide, heated to 160°—230°, yields, besides hydrochloric acid, an oily distillate, containing benzonitrile and chloride of benzyl, C^7H^7Cl (i. 573), and leaves a red-brown residue, which is separated, by digestion with alcohol at ordinary

Digitized by Google

temperatures, into a brown solution (A) and yellow flocks. The latter dis mixture of alcohol and chloroform, forming a solution which deposits two mo of lophine, $C^{21}H^{16}N^2$; the one crystallising in needles which melt at 230°, th needles which melt at 170° (see LOPHINE). The brown solution (A) yields two modifications of lophine just mentioned; secondly, a base, probably melting at 90°; thirdly, a base, $C^{21}H^{20}N^2$, which melts at 100°, forms a $C^{21}H^{20}N^2.C^2H^2O^4$, crystallising from alcohol in nacreous laminæ, and a plat $C^{21}H^{20}N^2.HCl.PtCl^2.2H^4O$, in microscopic prisms; fourthly, another modificat same base, whose platinum-salt is anhydrous; and fifthly, an oily base, forming a hydrochlorate, which melts at 220°, dissolves easily in water an and crystallises in six-sided prisms. (Ekman, *loc. cit.*—Kühn, N. Jahrb. P 292; Jahresber. 1861, p. 404.)

13. Hydrobenzamide heated with 2 at. *iodide of ethyl* to 80°—100°, yiel brown viscid mass, which, after purification by solution in alcohol, precip water, &c., is found to consist of di-iodide of tribenzylene-diethyl-dia

$[(C^7\ddot{H}^6)^3(C^2H^5)^2N^2]^2I^2$; and the alcoholic solution of this iodide, treated

of silver or hydrate of lead, yields the base $C^{25}H^{28}N^2O = [(C^7\ddot{H}^6)^3(C^2H^5)^2N^2$ base, again treated with iodide of ethyl, does not yield any distinct (Borodine, Ann. Ch. Pharm. cv. 257.)

Amarine, isomeric with hydrobenzamide, behaves differently with iodide yielding hydriodate of diethylamarine, $C^{21}H^{16}(C^2H^5)^2N^2.HI$, from which, by h potash, diethylamarine itself, $C^{21}H^{16}(C^2H^5)^2N^2$, may be obtained; and this b treated with iodide of ethyl, yields another base, which forms crystalline appears to contain a larger proportion of ethyl. This base is likewise acte iodide of ethyl, yielding a hydriodate just like the former. Hence B concludes that amarine contains at least 3 at. H, replaceable by ethyl, and it provisionally by the formula $N\begin{cases}N(C^7H^5)^3H.\\H^2\end{cases}$

Chloride of Hydrobenzamide, $C^{21}H^{18}N^2Cl^2$ (Th. Müller, Ann. C cxi. 144; Jahresber. 1859, p. 315), is produced by passing dry chlorine hydrobenzamide, which then takes up 19·5 per cent. chlorine, and melts t yellow liquid. It is decomposed by water, yielding sal-ammoniac, hydrochlor an oily mixture of hydride of benzoyl and benzonitrile, boiling between 180°

$$\underset{\text{Chloride of hydrobenzamide.}}{C^{21}H^{16}N^2Cl^2} + 2H^2O = \underset{\text{Hydride of benzoyl.}}{2C^7H^6O} + \underset{\text{Benzonitrile.}}{C^7H^5N} + NH^4Cl + HC$$

By anhydrous ether it is resolved into sal-ammoniac, and a mixture of b with an oily body which boils at 183°, and has the composition of chloroh mide (see below), but differs from that substance by its ready decomposibilit into benzonitrile and hydride of benzoyl.

Chloride of hydrobenzamide heated to 180°—200° is resolved into hydroc chlorohydrobenzamide, $C^{21}H^{17}ClN^2$, which distils over as a colourless oil, and which solidifies on cooling, and is resolved, by successive treatment with w and alcohol, into the following compounds:

The *aqueous* solution deposits on cooling a white powder, which sepa alcohol in hard granular crystals, consisting of $C^{21}H^{17}ClN^2.HCl$ or $C^{21}H^{18}N^2$ water the same compound crystallises with 1 at. H^2O. Ammonia added to t

throws down [? as a hydrate] the base $C^{28}H^{24}N^2 = N^2(C^7\ddot{H}^6)^4$, which may tetrabenzylene-diammonium. The chloroplatinate, $C^{28}H^{24}Cl^2N^2.PtC$ soluble.

The *ethereal* solution deposits crystalline needles insoluble in water, su 300°, and having the composition $C^{28}H^{21}N^3$.

The *alcoholic* solution yields crystals insoluble in water and in ether, and when dried over oil of vitriol, $C^{28}H^{22}N^3.HCl.2H^2O$. If the base be separate salt by ammonia, and redissolved in hydrochloric acid, the solution yields b tion a basic hydrochlorate, $2C^{28}H^{22}N^3.HCl.2H^2O$. The chloroplatinate, wh yellow, contains $2(C^{28}H^{22}N^3.HCl).PtCl^4$ (platinum, by experiment, 17·4 pe calculation, 17·9).

Chlorohydrobenzamide. $C^{21}H^{17}ClN^2$. (Th. Müller, *loc. cit.*)—Wh of hydrobenzamide is heated to 180°—200°, this compound distils over as a oil, heavier than water, and having a pungent odour of chlorine and b together. It dissolves easily in alcohol and in ether, and is slowly deco water, with formation of hydrochloric acid. When left in contact, for with a mixture of *nitric* and *sulphuric acids*, it forms a solution from w throws down crystallisable nitrobenzonitrile, $C^7H^4(NO^2)N$.

Digitized by Google

Chloronitro-hydrobenzamide. $C^{21}H^{15}Cl(NO^2)N^2$. (Müller, *loc. cit.*)—This compound is formed when chlorohydrobenzamide is left for 24 hours in contact with strong *nitric acid*, and is precipitated by water from the acid solution, as an oily very pungent liquid. It is soluble in alcohol, and the solution is decomposed by sulphide of ammonium, yielding benzonitrile and sulphobenzamide:

$$\underset{\text{Chloronitro-hydrobenz-amide.}}{C^{21}H^{15}Cl(NO^2)N^2} + 3H^2S = 2\underset{\text{Benzonitrile.}}{C^7H^5N} + \underset{\text{Sulphobenz-amide.}}{C^7H^7NS^2} + 2H^2O + HCl + S^2.$$

Hydrobenzile. $C^{14}H^{12}O$. (Zinin, J. pr. Chem. xxxiii. 35.)—A product of the action of sulphide of ammonium on benzile ($C^{14}H^{10}O^2$). It is insoluble in water, soluble in alcohol and ether, and crystallises from these solutions in the shape of concavo-convex lenses. The crystals melt at 47°, forming a colourless liquid, which distils without alteration, and solidifies in a crystalline mass at 42°. They have the smell of bitter almonds, and a saccharine pungent taste. They dissolve readily in sulphuric acid, and are precipitated therefrom by water. They are slowly attacked by chlorine, and not sensibly altered by boiling potash.

Hydrobenzoïn. $C^{14}H^{14}O^2$. (Zinin, Ann. Ch. Pharm. cxxiii. 125.)—A compound produced by the action of nascent hydrogen on benzoyl-hydride (bitter almond-oil), and containing the elements of 2 molecules of that compound ($C^{14}H^{12}O^2$), and 1 molecule of hydrogen, H^2. To prepare it, 4 pts. of bitter almond oil free from prussic acid are dissolved in 6 pts. alcohol of 85 per cent.; the solution is mixed with 4 pts. alcohol previously saturated with hydrochloric acid gas; and one pt. of finely-granulated zinc is carefully added, so that it may dissolve without perceptible evolution of hydrogen. When the reaction is finished, the liquid is heated to the boiling point, mixed after cooling with a small quantity of ether (to remove a body which adheres to the zinc and retards the action) and with 1 pt. more of alcohol saturated with hydrochloric acid gas, then heated to complete the reaction, and mixed with a quantity of water three or four times as great as that of the bitter almond oil taken. Hydrobenzoïn then separates as an oily body, which soon solidifies in a crystalline mass, and may be purified by washing in water, pressure between bibulous paper (to remove an acrid oil), and recrystallisation from alcohol (or if somewhat impure, previously from ether). It is thus obtained in large rhombic plates, which melt at 130°, and boil above 300°. When gently heated with 2 pts. nitric acid of specific gravity 1·36, it is converted, without any evolution of red vapours or formation of secondary products, into pure benzoïn; with stronger nitric acid, benzil is obtained. It is not attacked by potash, either aqueous or alcoholic, even at the boiling heat.

Hydroberberine. $C^{20}H^{21}NO^4$. (Hlasiwetz and Gilm. Ann. Ch. Pharm. Suppl. ii. 191; Rép. Chim. pure, 1863, p. 426.)—A base produced by the action of nascent hydrogen on berberine, as first observed by Hlasiwetz (Rép. Chim. pure, 1862, p. 367). It is obtained by boiling in a flask, provided with a condensing tube to cause the vapours to flow back, a mixture of 6 pts. berberine, 100 pts. water, 10 pts. distilled sulphuric acid, 20 pts. glacial acetic acid, a quantity of granulated zinc, and a few pieces of platinum foil. The liquid gradually loses its colour, and as soon as the froth exhibits a wine-yellow colour, which it does after boiling for an hour or two, the action is stopped, the liquid filtered, any crystalline deposits that may have formed are dissolved in dilute sulphuric acid, and an excess of ammonia is added after cooling. Hydroberberine is then obtained as a bulky yellowish deposit, which must be collected on a filter, washed, dried at a gentle heat, then pulverised, boiled in alcohol, and purified by repeated crystallisation from alcohol. Instead of precipitating the base by ammonia, it may be advantageously obtained as a hydrochlorate, by adding common salt to the original solution. The hydrochlorate is then almost wholly deposited in the form of a crystalline powder.

Hydroberberine may also be prepared by acting on berberine with sodium-amalgam, but it is then yellow and more difficult to purify.

Hydroberberine is deposited from a hot alcoholic solution, in small shining granular crystals, or flattened needles, which are colourless or slightly yellowish, and appear to belong to the monoclinic system. It differs from berberine, $C^{20}H^{17}NO^4$ (the formula lately determined by Perrins, Chem. Soc. J. xv. 339), by four additional atoms of hydrogen, and may be reconverted into that compound by the action of nitric acid. On dissolving it in a mixture of equal volumes of hydrochloric acid and alcohol, and dropping in nitric acid diluted with alcohol, the liquid becomes coloured, and deposits crystals of hydrochlorate of berberine.

Hydrochlorate of Hydroberberine. $C^{20}H^{21}NO^4.HCl$.—Crystals of hydroberberine spread upon a watch-glass, under a bell-jar within which hydrochloric acid is evolved, are converted into a white powder, consisting of the hydrochlorate, soluble in warm water, and crystallising in laminæ on cooling. The salt may also be obtained by

Digitized by Google

dissolving the base in hot hydrochloric acid; the solution on cooling forms a jelly, which is gradually transformed into crystals. It is more soluble in alcohol than in water. Its solutions yield copious precipitates with *chloride of platinum;* from a warm alcoholic solution, the platinum-salt is more gradually deposited in orange-yellow crystalline grains, consisting of $2(C^{20}H^{21}NO^4.HCl).PtCl^4$.

The *hydrobromate* and *hydriodate* are white, crystalline, and very slightly soluble.

The *nitrate*, which is also crystalline and very slightly soluble, is seldom obtained pure by dissolving the base in nitric acid, because the acid decomposes it; better by mixing a hot, very dilute solution of the sulphate with nitrate of sodium.—The *oxalate* crystallises in small rhombic plates, the *phosphate* in fine rhombic plates.

Sulphates of Hydroberberine. The neutral sulphate, $(C^{20}H^{21}NO^4)^2.H^2SO^4$, is obtained by dissolving an excess of the base in very dilute sulphuric acid. The liquid then deposits needles which fill it entirely, and after being expressed and purified by crystallisation, are very soluble in water, and contain a certain quantity of water, which they lose by exposure to the air; they likewise invariably contain a little free acid.

When the base is dissolved in a slight excess of acid, large transparent rhombohedrons are obtained, approaching nearly to the cube; they give off water when exposed to the air, and cannot be dissolved in water without decomposition. They appear to be a mixture of the neutral and acid sulphates, containing $4C^{20}H^{21}NO^4.3SH^2O^4.4H^2O$, or $\left.\begin{matrix}(C^{20}H^{21}NO^4)^2.SH^2O^4\\ 2(C^{20}H^{21}NO^4.SH^2O^4)\end{matrix}\right\}.4H^2O$.

A moderately dilute solution of this salt mixed with excess of sulphuric acid becomes turbid and deposits small mammellated crystals, or a resinous mass, which gradually changes into crystals of the acid salt, $C^{20}H^{21}NO^4.SH^2O^4$, which may be purified by recrystallisation from alcohol.

Tartrate of Hydroberberine forms mammellated groups of needles.

Ethyl-hydroberberine. $C^{22}H^{25}NO^4 = C^{20}H^{20}(C^2H^5)NO^4$.—Hydroberberine heated for some hours in a water-bath with an excess of iodide of ethyl, yields a pasty mass, which when taken up by alcohol, forms tufts of yellow rhomboïdal prisms, consisting of hydriodate of ethyl-hydroberberine, $C^{22}H^{26}NO^4.HI$, very soluble in water, and containing water of crystallisation, which they give off entirely at 100°. The mother-liquors of the preparation still yield small quadrangular laminæ of another substance, the admixture of which with the first crystals must be avoided.

HYDROBORACITE. *Hydrated Borate of Calcium* and *Magnesium.* $\left.\begin{matrix}3CaO\\ 3MgO\end{matrix}\right\}8B^2O^3.18H^2O$.—Resembles fibrous and foliated gypsum. Colour white with spots of red, from iron. Translucent in thin plates. Melts before the blowpipe to a clear glass, tinging the flame slightly green and not becoming opaque. Heated in a tube it yields water. It is slightly soluble in water, the liquid having a faint alkaline reaction. It dissolves readily in nitric and hydrochloric acids. It was found by Hess (Pogg. Ann. xxxi. 49) in a collection of Caucasian minerals.

HYDROBOROCALCITE. Syn. with BOROCALCITE.

HYDROBROMIC ACID. See BROMIDE OF HYDROGEN (i. 672).

HYDROBRYOTIN. $C^{42}H^{74}O^{16}$.—An amorphous substance, insoluble in ether, but soluble in alcohol, produced by the decomposition of bryonin (i. 685).

HYDROBUCHOLZITE. See KYANITE (p. 449).

HYDROCALCITE. Hydrated carbonate of calcium, $CaCO^3.5H^2O$. Found in small rhombohedral crystals, forming an incrustation on wood under water. (See CARBONATES.)

HYDROCARBONS. Compounds consisting of carbon and hydrogen only. The number of bodies of this class at present known is very great, but the most important of them may be arranged in the following groups:

1. Alcohol-radicles	. . $(C^nH^{2n+1})^2$	homologous with	Methyl $(CH^3)^2$
2. Hydrides of alcohol-radicles	. . C^nH^{2n+2}	,,	Marsh-gas (CH^4)
3. Olefines	. . C^nH^{2n}	,,	Ethylene or Olefiant gas (C^2H^4)
4. Hydrocarbons	. . C^nH^{2n-2}	,,	Acetylene (C^2H^2)
5. Camphenes or Terebenes	C^nH^{2n-4}	isomeric with	Turpentine, $C^{10}H^{16}$
6. Hydrocarbons	. . C^nH^{2n-6}	homologous with	Benzene (C^6H^6)
7. Hydrocarbons	. . C^nH^{2n-12}	,,	Naphthalene, $C^{10}H^8$

The most fruitful source of hydrocarbons is the dry or destructive distillation of organic bodies, the nature of the products varying according to the temperature at which

Digitized by Google

us, coal when distilled at a bright red, as for the hydrocarbons belonging to the second, third, fourth r with a considerable quantity of naphthalene; but ure at which complete decomposition can take place ng chiefly to the second and third groups, together ch probably also belongs to the second group. The s buried beneath the surface of the earth has also ons belonging to the second group, as shown by the nd in certain parts of North America, which, as lmost wholly of alcoholic hydrides of the general

ydrochloric acid, hydrobromic acid, &c. Wurtz 14) that amylene combines with hydrobromic and omeric with iodide and bromide of amyl; and by th moist oxide of silver, he has obtained a hydrate amylic alcohol. All these compounds are dis- with which they are isomeric, by the facility with er the influence of various reagents. Thus hydrate ic acid gas, and is resolved into hydriodate of d; similarly with hydrochloric acid. Bromine de of amylene and water; chlorine similarly but the compound $C^5H^{10}.NaHO$, which when treated ields amylene, hydrate of amylene, and iodide of

$$HI = C^5H^{10} + C^5H^{10}.H^2O + NaI.$$

decomposed by sodium, yielding iodide of sodium, lcoholic potash, it yields amylene and iodide of ucts are iodide of ammonium, amylene, and a erhaps identical with amylamine.

Digitized by Google

The amylene in all these compounds appears to be but loosely united with the w or the acid, and is set at liberty on the slightest disturbance; whereas in their ison the amyl-compounds, the group C^5H^{11}, which is not capable of existing in the sepa state, is easily transferred from one compound to another, and it is only with consi able difficulty that two molecules of it can be made to coalesce into one so as to f free amyl, $C^{10}H^{22}$.

Hexylene, C^6H^{12}, also unites with hydriodic acid, and the hydriodate, treated w water and oxide of silver, yields a hydrate, $C^6H^{12}.H^2O$, isomeric with hexylic alcohol, possibly identical with the β hexylic alcohol discovered by Wanklyn and Erlenmey

The formation and properties of the alcohol-radicles (i. 96) and their hydri (iii. 180) have already been considered. Recent investigations seem to show that th is no essential difference between the alcohol-radicles in the free state, and th hydrides (pp. 144, 182).

Of the hydrocarbons, C^nH^{2n-2}, homologous with acetylene, only three have b obtained, viz. acetylene, C^2H^2 (i. 1111), allylene, C^3H^4 (i. 1112), and croton lene, C^4H^6 (ii. 965).

Of the hydrocarbons, C^nH^{2n-6}, homologous with benzene, five are known, viz. benze C^6H^6 (i. 541), benzylene or toluene, C^7H^8 (i. 577), xylene, C^8H^{10}, cumene, C^9 (ii. 173), and cymene, $C^{10}H^{14}$ (ii. 296). They have all been specially considered, exce ing xylene, which will be described in its place. These hydrocarbons, as already observ are produced by the destructive distillation of coal and other organic substances at h temperatures; also in a great variety of chemical reactions (see Benzene). They distinguished by the facility with which they form substitution-compounds with conc trated nitric acid, *e.g.* nitrobenzene, $C^6H^5(NO^2)$. These nitro-compounds, being hea oily liquids of rather high boiling point, afford the means of separating these hyd carbons from others, such as the alcoholic hydrides, with which they may be mix (p. 146). The same compounds subjected to the action of reducing agents, such sulphydric acid or ferrous acetate, yield organic bases, which may be supposed to derived from the nitro-compound by substitution of amidogen, NH^2, for nitryl, N *e.g.* aniline, $C^6H^5(H^2N)$, from nitrobenzene.

The camphenes, or terebenes, $C^{10}H^{16}$, isomeric with oil of turpentine, exist rea formed in a great number of plants. For their general properties see vol. i. p. 724

The hydrocarbons are the simplest of all organic compounds, and may be regard as the starting-points from which all others may be derived, by substitution or ad tion (see Nucleus-theory and Radicles). Hence, of late years, the attention chemists has been very much directed to the discovery of methods for producing th compounds directly from their inorganic elements; since, when this is accomplish the formation of a great number of the more complex organic compounds, by t synthesis of their elements, becomes a comparatively easy matter. The most su cessful efforts in this direction have been made by Berthelot (Chem. Soc. J. xvii. 3 who has succeeded in producing certain hydrocarbons by direct combination of t elements carbon and hydrogen, and from these producing others of great complexity

1. Acetylene, C^2H^2, is produced when hydrogen is passed over carbon heated bright redness by the electric arc. This gas, passed into a solution of cuprous chlori forms cuprous acetylene, $C^2(Cu^2)''H^2$; and this compound, subjected to the acti of nascent hydrogen (evolved by the action of zinc on ammonia), yields ethylene

$$\underset{\text{Acetylene.}}{C^2H^2} + H^2 = \underset{\text{Ethylene.}}{C^2H^4}$$

Ethylene thus obtained may be converted into alcohol, and from this a host of oth compounds, ethers, acetones, acids, amines, &c. may be derived.

2. Hydrocarbons may be formed from inorganic compounds containing their e ments, such as water and sulphide of carbon, or carbonic anhydride. A mixture sulphydric acid and sulphide of carbon, subjected to the action of copper at a re heat, yields marsh-gas:

$$CS^2 + 2H^2S + 4Cu = CH^4 + 4CuS.$$

Marsh-gas may also be formed from carbonic anhydride, though by a less direct pr cess, viz. by first converting the latter compound into carbonic oxide, this into form acid ($CO + H^2O = CH^2O^2$, ii. 683), then subjecting a salt of this acid, the barium salt, for example, to dry distillation:

$$2C^2H^2BaO^4 = CH^4 + CO^2 + 2BaCO^3.$$

Marsh-gas, mixed with an equal volume of chlorine, yields chloride of methyl, CH^3 and this ether distilled with potash, yields methylic alcohol, CH^4O, which is form by the addition of 1 at. oxygen to marsh-gas, whereas ethylic alcohol is formed fr ethylene by the addition of the elements of water. These two modes of formation

Digitized by Google

alcohols from hydrocarbons are general, the former applying to all homologues of marsh-gas, the latter to all homologues of ethylene.

3. A hydrocarbon may be transformed into another of greater complexity: *a*. By *direct condensation*. Marsh-gas raised to a very high temperature, or subjected to the action of a series of induction-sparks, is converted into acetylene, which contains twice the quantity of carbon in the same volume: $2CH^4 = C^2H^2 + H^4$. The condensation of marsh gas may, however, be carried considerably further, and made to yield naphthalene, a hydrocarbon containing ten times as much carbon in the same volume: $10CH^4 = C^{10}H^8 + H^{32}$ viz. by enclosing the marsh-gas in a tube of very refractory glass, and keeping it for several hours at a temperature as near as possible to that at which Bohemian glass softens. The condensation may also be effected by subjecting the vapour of bromoform, $CHBr^3$ (tribrominated methylic hydride), to the action of copper at a red heat, so as to remove the bromine. The residue, CH, then suffers a six-fold condensation, yielding benzene, C^6H^6.

b. By the union of two simple molecules into a more complex molecule. Thus, when a mixture of marsh-gas and carbonic oxide is slowly passed through a tube heated to low redness, tritylene, C^3H^4, is produced:

$$2CH^4 + CO = C^3H^4 + H^2O.$$

This reaction may perhaps explain the formation of a small quantity of tritylene in the distillation of formate of barium; and it is doubtless to reactions of the same order that we may attribute the production of hydrocarbons of the same series, which has been experimentally demonstrated as high as amylene, in the distillation of acetates.

There are also other ways in which complex hydrocarbons may be built up by the union of those of more simple constitution. Wurtz has shown (Ann. Ch. Pharm. cxxiii. 202; cxxvii. 55), that amylene, C^5H^{10}, may be produced by the union of the alcohol-radicles ethyl and allyl:

$$C^2H^5 + C^3H^5 = C^5H^{10},$$

this combination being brought about by the mutual action of zinc-ethyl and iodide of allyl. A number of other hydrocarbons are, however, formed at the same time, the following having been isolated and analysed:

C^2H^4	C^3H^6	C^5H^{10}	C^5H^{12}	C^6H^{10}	$C^{10}H^{20}$
Ethylene.	Tritylene.	Amylene.	Hydride of amyl.	Allyl.	Decatylene.

The ethylene and tritylene are produced by the mutual action of the ethyl and allyl groups:

$$C^2H^5 + C^3H^5 = C^2H^4 + C^3H^6.$$

Decatylene, $C^{10}H^{20}$, results from the condensation of two molecules of amylene into one. Besides these compounds, there are also formed other hydrocarbons, boiling above 200° (decatylene, the least volatile of those above-mentioned, boils at 160°), and containing, like allyl, a smaller proportion of hydrogen than the olefines. The formation of these hydrocarbons explains that of hydride of amyl, in which the proportion of hydrogen is larger than in the olefines.

The hydrocarbon, C^5H^{10}, obtained in the reaction just described, possesses the principal physical and chemical properties of amylene produced from amylic alcohol by the action of chloride of zinc, and, therefore, is not merely an isomer (ethyl-allyl) of that compound. This formation of amylene from two hydrocarbons of lower molecular weight is analogous to that of chloride of heptyl, $C^7H^{15}Cl$, by the action of chlorine on ethyl-amyl, $C^2H^5.C^5H^{11}$, and of chloride of decatyl, $C^{10}H^{21}Cl$, by that of chlorine on amyl itself, observed by Schorlemmer.

HYDROCARBOXYLIC ACIDS. (Lerch, Ann. Ch. Pharm. cxxiv. 20; Rép. Chim. pure, 1863, p. 143; Jahresb. 1862, p. 276.)—This name is applied to three acids produced, together with others, by the decomposition of carboxide of potassium, the black amorphous substance formed in the preparation of potassium in the ordinary way, and likewise by the direct combination of potassium with carbonic oxide. This substance remains unaltered when kept in rock-oil or in a dry vacuum, but when exposed to the air, it absorbs moisture rapidly, acquiring a cherry-red and finally a yellow colour: it absorbs oxygen only when moist. When treated with water, alcohol or ether, out of contact with the air, it gives off gas, and leaves a black glutinous substance, which turns red on exposure to the air, and dissolves in water with red colour and without disengagement of gas. This mass yields, besides oxalic acid, three series of acids, including croconic acid (ii. 109).

Perfectly unaltered carboxide of potassium, to which Brodie assigns the formula C^6K^2, yields, when treated with hydrochloric acid, an acid crystallising in white needles and having the composition $C^{10}H^{10}O^{10}$; this is trihydrocarboxylic acid.

If the carboxide of potassium be first treated with alcohol and then with hydrochloric acid, it yields black needles of dihydrocarboxylic acid, $C^5H^4O^5$ or $C^{10}H^8O^{10}$.

Digitized by Google

If the air has had access to the mass before or after the treatment with afterwards yields, with hydrochloric acid, dark garnet-red crystals of h boxylic acid, $C^{10}H^6O^{10}$.

Lastly, if the mass has been left in contact with the air till it has turned qui it is then treated with hydrochloric acid, a fourth acid is obtained, called ca acid, the potassium-salts of which are composed according to the formulæ and $C^{10}K^4O^{10}$. On attempting to isolate this acid, fine colourless prisms of rh acid, $C^5H^4O^6$, are obtained, being derived from the preceding by fixation of splitting up of the molecule:

$$C^{10}H^4O^{10} + 2H^2O = 2C^5H^4O^6.$$

In addition to these acids, croconic acid, $C^5H^2O^5$ (formed from carboxyl division of the molecule), and oxalic acid, are obtained as final products of tion.

The formation of dihydrocarboxylic, hydrocarboxylic, and carboxylic acids tion of trihydrocarboxylic acid is represented by the following equations:

$$C^{10}H^8O^{10} + O = C^{10}H^8O^{10} + H^2O.$$
$$C^{10}H^6O^{10} + O = C^{10}H^6O^{10} + H^2O.$$
$$C^{10}H^6O^{10} + O = C^{10}H^4O^{10} + H^2O.$$

Trihydrocarboxylic acid. $C^{10}H^{10}O^{10} = \left.\begin{matrix} C^{10}H^6O^6 \\ H^4 \end{matrix}\right\} O^4$.—This acid is pr already observed, by the action of hydrochloric acid on carboxide of potassi has not been exposed to the air; also by the reduction of dihydrocarboxylic forms white silky needles which, when exposed to moist air, quickly turn re ultimately converted into dihydrocarboxylic acid. Its solution is acid, colou very sensitive to the action of oxidising agents. By nitrate of potassium, it is into oxycarboxylic acid, with evolution of nitrogen. Of the 10 at. hydrogen in its molecule, 6 at. are easily removed by oxidation, giving rise to new rad those of dihydrocarboxylic, hydrocarboxylic and carboxylic acids, whereas the 4 at. are basic, and easily replaceable by metals, but not removable by oxida the potassium-salt also, $C^{10}K^4O^{10}$, 6 at. K may be removed, two at a time, by whereas the remaining 4 at. K appear to be irremovable: hence the rationa of the acid above given. In like manner, dihydrocarboxylic acid contains hydrocarboxylic acid, 2 at. H, removable by oxidation.

The trihydrocarboxylates of the alkali-metals are soluble in water, the o are sparingly soluble or insoluble: they all become coloured by exposure t yielding salts of the following acids:

Dihydrocarboxylic acid. $C^{10}H^8O^{10} = \left.\begin{matrix} C^{10}H^4O^6 \\ H^4 \end{matrix}\right\} O^4$.—This acid for metallic-shining monoclinic crystals, grouped in very thin tufts; the thinne have a wood-yellow colour, and exhibit trichroïsm. They are permanent i even at 100°, dissolve readily in water and alcohol, slowly in ether; the sol red by transmitted, violet by reflected light.

The salts of this acid are as unstable as those of the preceding. Those of t metals are black, soluble in water and crystallisable; the rest are blue or red pre they are very easily converted by oxidation into rhodizonates or carboxylates

Hydrocarboxylic acid, $C^{10}H^6O^{10} = \left.\begin{matrix} C^{10}H^2O^6 \\ H^4 \end{matrix}\right\} O^4$, was obtained accide the preparation of the preceding acid from a black mass which had undergo alteration. It crystallises from alcohol in long brown needles, which in con water are immediately resolved into dihydrocarboxylic and rhodizonic acids:

$$2C^{10}H^6O^{10} + 2H^2O = C^{10}H^8O^{10} + 2C^5H^4O^6.$$

HYDROCAROTIN. $C^{18}H^{30}O$. (Husemann, Ann. Ch. Pharm. cx Jahresber. 1861, p. 754).—A substance contained, together with carotin (i. 8 root of the carrot (*Daucus carota*). To obtain these substances, the crushe are pressed, the residue is repeatedly washed out with water, and the united sol mixed with a little dilute sulphuric acid and tincture of galls (which facil separation of the coagulum); the glutinous precipitate, freed by pressure fro closed liquid, is boiled six or seven times in the half-dry state with 5 o alcohol of 80 per cent.; and the residue is treated with sulphide of carbon to e carotin. The alcoholic extract contains hydrocarotin together with manni carrots are a year old, but not if they are fresh), sugar, a fixed oil, and a small carotin.

Hydrocarotin crystallises from the alcoholic extract, after long standing, i crystals, which may be freed from mannite (if present) by recrystallisa

Digitized by Google

hot alcohol, and finally by boiling with water. It is tasteless and inodorous, crystallises in large colourless silky laminæ, from ether in flat rhombic prisms; is lighter than water (which does not wet it); melts at 126·8°; dissolves in alcohol, and more easily in ether, sulphide of carbon, benzene, volatile oils, and chloroform. When heated above 100°, it turns yellow to yellowish red; after fusion it remains amorphous, and then dissolves less easily in benzene and sulphide of carbon.

Hydrocarotin is not precipitated from its alcoholic solution by metallic salts or tannic acid; it is not altered by the action of caustic alkalis, strong acids, or oxidising agents: with *fuming nitric acid*, it appears to form a nitro-compound. Strong *sulphuric acid* colours it red and dissolves it completely at a gentle heat, forming a solution from which it is precipitated by water apparently unaltered, but in the amorphous state. With *chlorine* it forms a resinous substitution-product, $C^{18}H^{26}Cl^4O$; with *bromine* a similar body, $C^{18}H^{27}Br^3O$, whose ethereal solution, when treated with alcoholic potash, gives up bromine, and forms a yellowish-red substance soluble with blood-red colour in sulphide of carbon. *Iodine* also, in sunshine, appears to form a substitution-product with hydrocarotin.

HYDROCERITE. See LANTHANITE.

HYDROCHINONE. See HYDROQUINONE.

HYDROCHLORE. See PYROCHLORE.

HYDROCHLORIC ACID. See CHLORHYDRIC ACID (i. 890).

HYDROCHRYSAMIDE. $C^7H^6N^2O^2$. (Schunck, Ann. Ch. Pharm. lxv. 231.)—A compound produced by the action of reducing agents on chrysammic acid (i. 955). It may be prepared by adding chrysammic acid to a boiling solution of sulphide of potassium containing excess of caustic potash; or to a boiling solution of protochloride of tin, afterwards removing the excess of acid, dissolving the residue in boiling potash, and leaving the solution to crystallise. It is difficult, however, by the latter method to obtain it free from oxide of tin.

Hydrochrysamide forms needle-shaped crystals, of a fine blue colour by transmitted, and metallic red by reflected light. Heated in a small tube, it gives off violet vapours, which condense in crystals on the cold parts of the tube; the greater part, however, is decomposed, giving off ammonia and leaving charcoal. It is insoluble in boiling *water*, and sparingly soluble in boiling *alcohol*, to which it imparts a faint blue tint. It is dissolved by strong *sulphuric acid*, and reprecipitated in blue flakes by water.—It is decomposed by boiling *nitric acid*, and by *chlorine* in presence of water. It dissolves in *potash* and in *alkaline carbonates*, forming solutions of the colour of sulphindigotic acid; acids precipitate it therefrom in blue flakes.

HYDROCINNAMIDE. $C^{27}H^{24}N^2 = N^2(C^9H^8)^3$. *Cinnhydramide. Hydride of Asocinnamyl.* (Laurent, Rev. scient. x. 119.)—Produced by the action of ammonia on hydride of cinnamyl:

$$3C^9H^{10}O + 2NH^3 = N^2(C^9H^8)^3 + 3H^2O.$$

When purified by recrystallisation from hot alcohol and ether, it forms colourless right prisms with rectangular base, but having their bases replaced by two triangular facets, meeting at a very obtuse angle. It is inodorous, insoluble in water, fusible, and solidifies on cooling to a transparent amorphous mass like gum. It is decomposed by distillation, yielding an oil and a solid substance. It is not decomposed by boiling hydrochloric acid, or by alcoholic potash; but boiling nitric acid decomposes it, yielding a product which melts in boiling water.

Dumas and Peligot, by treating oil of cinnamon with dry ammonia gas, obtained a product which crystallised from alcohol and ether in silky tufts, and to which they assigned the formula $C^9H^{10}O.NH^3$, but it probably consisted mainly of hydrocinnamide. (*Gerhardt's Traité*, iii. 385.)

HYDROCOTYLE ASIATICA. A plant used in India as a remedy against various cutaneous diseases. According to Lepire (J. Pharm. [3] xxviii. 47), it contains a peculiar principle, *vellarin* (from the Tamul name of the plant, *vallâraï*), which he describes as a bitter, strong-smelling oil, soluble in weak alcohol and in ether, thickening on exposure to the air, soluble in aqueous ammonia, insoluble in potash.

HYDROCROCONIC ACID. $C^5H^4O^5 = \left.\begin{matrix}C^5H^2O^3\\H^2\end{matrix}\right\}O^2$. (Lerch, Ann. Ch. Pharm. cxxiv. 20.)—An acid produced by the action of hydriodic acid on croconate of potassium in closed vessels. On mixing the product of the reaction with alcoholic potash-solution, hydrocroconate of potassium, $C^5H^1K^2O^5$, separates as a dingy red precipitate, which crystallises from hot water in crimson needles. The blood-red solution of this

Digitized by Google

salt is converted into croconate (and a small quantity of oxalate) of potassiu exposure to the air, especially in presence of alkali.

Hydrocroconic acid is soluble in water, alcohol, and ether, and does not cryst The *barium-salt*, $C^5H^2Ba''O^5$, is a pæony-red precipitate, soluble in hydroc insoluble in acetic acid. The *lead-salt*, $C^5H^2Pb''O^5$, is also a red precipitate.

HYDROCYANHARMALINE. See HARMALINE (p. 8).

HYDROCYANIC ACID. See CYANIDE OF HYDROGEN (ii. 214).

HYDRODOLOMITE. A hydromagnesite, having part of the magnesium re by calcium. Occurs on Somma in isolated, sinter-like, globular or stalactitic, masses, having a white or yellowish white colour. According to Kobell (J. pr. xxxvi. 304), it contains 25·22 per cent. lime, 24·28 magnesia, 33·10 carbonic anhy and 17·40 water: whence the formula $3[(Mg; Ca)''CO^3.H^2O] + Mg''H^2O^2$. (K melsberg.)

HYDRO-ELECTRIC MACHINE. See ELECTRICITY (ii. 408).

HYDROFERRICYANIC ACID. See FERRICYANIDES (ii. 244).

HYDROFERROCYANIC ACID. See FERROCYANIDES (ii. 226).

HYDROFLUOBORATES. See BORON, FLUORIDE OF (i. 632).

HYDROFLUOSILICATES. See SILICON, FLUORIDE OF.

HYDROGALACTOMETER. An arrangement described by Zen (Jahrb. pr. Pharm. xx. 65; Jahresb. 1850, p. 619) for determining the amou water added to normal milk. The milk is coagulated by a few drops of hydroc acid, and the volume of the curd, separated by filtration through flannel, is com with that obtained in a similar manner from pure milk.

HYDROGEN. *Atomic weight* = 1. *Symbol* H. (*Inflammable air*, *Wasse Hydrogenium.*)—The older alchemists do not appear to have been acquainted wit gas. The evolution of an air during the solution of iron in sulphuric acid wa noticed in the sixteenth century by Paracelsus. The inflammability of the ai produced, was observed in the seventeenth century by Turquet de Mayern afterwards (1672) by Boyle, in his "New Experiments touching the relation be Flame and Air." Lemery in 1700 observed the detonating property of this in mable gas. But the first exact experiments on its nature were made in 17 Cavendish, who showed that it is a peculiar kind of air, which he called *inflam air;* that it is produced when iron, zinc, or tin is dissolved in dilute sulphu hydrochloric acid; and that different metals evolve different quantities of the gas also estimated its specific gravity at $\frac{1}{11}$ of that of common air. (It is really about

The inflammable air generated in these processes was, however, for some time founded with other kinds of inflammable air, such as those produced by the destru distillation of organic bodies, by the imperfect combustion of charcoal—with vap ether, &c., all of which were supposed to consist essentially of the same inflam principle modified by the admixture of other substances. Moreover, it was sup that the inflammable principle developed in the solution of metals in acids, proc from the metal, and that it was either phlogiston or intimately related thereto.

The production of moisture in the burning of hydrogen, appears to have bee noticed by Macquer and De la Metherie, in 1766; but no one at that time posed that the only product of the combustion was water. Lavoisier supposed hydrogen, like other combustible bodies, produced an acid in burning, and made se unsuccessful experiments to obtain this acid. But the grand discovery that wa the sole product of the combustion of hydrogen was made by Cavendish, in and published in 1783. Cavendish showed that 423 volumes of hydrogen requir combustion 1,000 volumes of air (which contain 210 volumes of oxygen, and will, t fore, burn exactly 420 volumes of hydrogen); and, moreover, that when hydroge oxygen gases are burnt together in certain proportions, nearly all the gas disap nothing but slight impurities remaining behind. These results were afterwards confirmed by the experiments of Lavoisier and Laplace (see GAS, ii. 780).

Sources.—Hydrogen is never found in the free state. The compound which co it in the greatest abundance is marsh-gas, of which it forms one-fourth. Of wa forms one-ninth. It occurs in smaller quantities in combination with phosph sulphur, iodine, bromine, carbon and nitrogen, and is an essential constituent of n all organic compounds.

Preparation.—Hydrogen is generally obtained by the decomposition of water, dilute acids.—1. It is produced in the state of greatest purity by electrolysis, as al explained in the article ANALYSIS OF GASES (i. 285).

2. By passing vapour of water over iron nails or wire contained in a gun-barrel horizontally in a furnace, and heated to bright redness. The iron is thereby conv

Digitized by Google

into ferroso-ferric oxide, Fe^3O^4, while hydrogen gas passes over, and may be collected over water.

3. By introducing potassium or sodium into an inverted tube or cylinder filled with water or alcohol, and standing in a vessel of the same liquid. It is best to wrap the metal in a piece of paper before plunging it under the mouth of the cylinder:

$$\underset{}{H^2O} + Na = \underset{\text{Hydrate of sodium.}}{NaHO} + H.$$

$$\underset{\text{Alcohol.}}{C^2H^6O} + Na = \underset{\text{Ethylate of sodium.}}{C^2H^5NaO} + H.$$

4. By dissolving zinc or iron in sulphuric acid diluted with an eight-fold quantity of water, or in hydrochloric acid diluted with twice its weight of water:

$$H^2SO^4 + Zn = ZnSO^4 + H^2,$$

and

$$2HCl + Zn = ZnCl^2 + H^2.$$

This is the most convenient method of obtaining the gas for general purposes.—5. By dissolving zinc, in contact with iron or platinum, in solution of caustic potash, zincate of potassium being then formed:

$$\underset{\text{Hydrate of potassium.}}{2KHO} + Zn = \underset{\text{Zincate of potassium.}}{ZnK^2O^2} + H^2.$$

The use of the iron is to form an electric couple with the zinc, the latter then acting on the positive or active metal.

6. By acting on cuprous hydride with hydrochloric acid:

$$Cu^2H^2 + 2HCl = Cu^2Cl^2 + 2H^2.$$

7. By heating formates or oxalates with excess of hydrate of potassium, sodium, or calcium:

$$\underset{\text{Formate of potassium.}}{CHKO^2} + KHO = \underset{\text{Carbonate of potassium.}}{CK^2O^3} + H^2.$$

$$\underset{\text{Oxalate of potassium.}}{C^2K^2O^4} + 2KHO = 2CK^2O^3 + H^2.$$

8. By the action of hydrate of potassium on certain organic bodies having a tendency to form acids by oxidation:

$$\underset{\text{Hydride of benzoyl.}}{C^7H^6O} + KHO = \underset{\text{Benzoate of potassium.}}{C^7H^5KO^2} + H^2.$$

Purification.—Hydrogen prepared by dissolving zinc or iron in sulphuric acid—which is the method most used—may contain the following impurities:—1. *Sulphurous acid*, if this acid is present in the sulphuric acid used.—2. *Nitrous oxide* or *nitric oxide gas*, if the sulphuric acid contains nitric oxide, nitrous acid, or nitric acid.—3. *Sulphydric acid*, if the zinc contains sulphide of zinc, or if the sulphuric acid contains sulphurous acid—or if a fresh quantity of strong sulphuric acid be added to the dilute acid already acting on the zinc, without mixing it well with the liquid.—4. *Phosphoretted hydrogen*, if the zinc contains phosphorus.—5. *Arsenetted hydrogen*, if the zinc contains arsenic, or if the sulphuric acid contains arsenious acid.—6. *Carbonic anhydride* has occasionally been observed in hydrogen prepared with peculiar kinds of zinc. These impurities, which give the gas an unpleasant odour, may be removed by passing it over substances which absorb or decompose the adventitious gases. Dumas passed the gas through two U-tubes, each about three feet long, and filled with broken glass, the glass in the first tube being moistened with nitrate of lead, which removes the sulphydric acid, and that in the second with sulphate of silver, by which the arsenetted hydrogen is separated; then through a third U-tube filled with fragments of pumice-stone saturated with strong potash; and, lastly, to render it anhydrous, first through a tube containing fragments of hydrate of potassium, then through another containing phosphoric anhydride or pumice-stone soaked in oil of vitriol. To avoid the presence of oxides of nitrogen, it is best to use sulphuric acid perfectly free from those oxides.

Hydrogen gas obtained by the use of iron may contain the same impurities as that prepared with zinc—and in addition:—1. *Ferruretted hydrogen*—to be removed by fuming nitric acid or solution of mercuric chloride; and 2. The vapour of an oily hydrocarbon, which is produced in larger quantity as the iron contains more carbon, and communicates a peculiarly repulsive odour to the gas. It may be removed by passing the gas through alcohol, and the alcohol may be afterwards separated by water.

Digitized by Google

cording to Döbereiner (Schw. J. iii. 377), the gas obtained with either zinc or iron
ıy be deprived of all odour by 24 hours' contact with moistened charcoal powder.
In whatever manner the gas may be prepared, it generally contains a small quantity
atmospheric air, proceeding from the liquids used in the preparation. The nitrogen
nnot be removed; but the oxygen may be separated by leaving the gas for a while
contact with spongy platinum, which causes the oxygen to unite with a portion of
hydrogen and form water.

Properties.—Hydrogen is a colourless gas, of specific gravity 0·0693. It is the
htest of all known substances, being about 14½ times as light as atmospheric air; it
ıy therefore be used for inflating balloons. Soap-bubbles filled with it rise rapidly
the air. It escapes rapidly out of vessels with their mouths turned upwards; but a
de-mouthed vessel filled with it may be carried with its mouth downwards for a
ısiderable distance without the gas escaping. For the same reason, it is easily
llected by displacement, without the use of water, viz. by holding the vessel which
to receive it, over the extremity of a vertical tube attached to the mouth of the
ıerating vessel.

Hydrogen is odourless when quite pure, but as usually prepared, it has a disagreeable
our, arising from impurities. Small animals introduced into the gas die instantly.
man, the pure gas excites, after two inspirations, disagreeable sensations and loss
muscular power; when mixed with air, it may be breathed for a longer time, but
parts a peculiar squeaking tone to the voice. It is not directly injurious, but so long as
s inhaled, oxygen gas, which is essential to life, is prevented from entering the lungs.
Hydrogen is very inflammable, and burns in the air with a pale blue flame. It does
support the combustion of those bodies which burn in the air: for instance, if a jar
l of hydrogen be held with its mouth downwards, and a lighted taper plunged into
the hydrogen will be set on fire at the mouth, but the taper will be extinguished.
jet of oxygen will, however, burn in hydrogen, as well as a jet of hydrogen in oxygen,
ough with a somewhat different appearance. The experiment may be made by
ting fire to hydrogen-gas at the mouth of a bottle, and then directing a jet of oxygen
ough the flame into the body of the gas. A flame will then be formed at the orifice
the jet, and will continue to burn till the hydrogen is exhausted.

Hydrogen and *oxygen* unite to form water, in the proportion of 2 volumes of hydrogen
l volume of oxygen; and when the gases are mixed in these proportions, they may
made to unite, either slowly or rapidly, the entire volume of gas disappearing. On
nging a burning body in contact with the mixture, or passing an electric spark
ough it, combination instantly takes place throughout the whole mass, attended
h great and sudden rise of temperature, whereby the mixed gases, or rather the
tery vapour resulting from their union, are expended with a force sufficient to shatter
containing vessel, if not of great strength. If the vessel is entirely closed, and
ng enough to resist the expansive force of the gas, no noise is heard; but if the
uth of the vessel be left open, or the gas be able to force for itself a passage into the
a loud detonation is the result, arising from the concussion of the air by the
aping gases. The same effect is produced, though with much less intensity, when a
xture of 2 vol. hydrogen and 5 vol. atmospheric air (containing 1 vol. oxygen, the
ntity required to unite with 2 vol. hydrogen) is exposed to the action of flame or
electric spark. Hence, in manipulating with hydrogen, great care must be taken
prevent accidental admixture of air, as, if such admixture takes place unknown to the
rator, explosions of dangerous character may ensue when the gas comes in contact with
ne. In collecting the gas, a considerable quantity should be suffered to escape before
of it is collected, so that the air in the apparatus may be completely eliminated.

The rapid combination of hydrogen and oxygen may be brought about, not only by
contact of flame, but also by the heat of a red-hot iron wire, or a coal hot enough to
ibit a visible glow by daylight. According to Biot (Gilb. Ann. xx. 99), the heat
duced by suddenly compressing the detonating gas, is sufficient to cause the explosion.
The presence of certain metals causes the gases to unite, even at ordinary tempera-
es. This effect is exhibited most strikingly by platinum, in the form of platinum-
nge or platinum-black (see PLATINUM); but it is also produced by a plate of the
tal rendered perfectly clean by rubbing it while hot with fused potash, then washing
vith water, dipping it into hot oil of vitriol, and again washing with water. Similar
cts are exhibited, though with less facility, by spongy iridium and osmium, finely
ided palladium, gold in the form of leaves or dust, and silver leaf. This peculiar
ion of platinum and other metals appears to be due (in part at least) to the absorp-
n of the gases by the metal, and their condensation within its pores. (See GASES, SORPTION OF, BY SOLIDS, ii. 804.)

The flame of hydrogen, though but feebly luminous, is intensely hot, and when a jet
oxygen is directed through it, as in the oxy-hydrogen blowpipe, the proportions of
two gases being properly adjusted so that neither of them is in excess, the heat

Digitized by Google

obtained by chemical combination. (See Blow-

Dioxide, or Peroxide of Hydrogen. HO or H^2O^2.—This remarkable compound was discovered by Thénard (*Traité de Chimie*, 4me. éd. iv. 2, 41).—It is produced when peroxide of potassium, sodium, barium, strontium, or calcium is digested in any acid which forms a soluble salt with the base resulting from the decomposition of the peroxide, the excess of oxygen not escaping as gas, but passing over to a portion of the water, and converting it into peroxide of hydrogen, *e.g.*:

$$BaO + HCl = 2BaCl + HO.$$

Preparation.—Pure baryta is prepared by igniting, in a porcelain retort, nitrate of barium free from iron and manganese. The baryta, broken into pieces about the size of a nut, is then put into a coated glass tube and heated to low redness, while a current of oxygen gas free from carbonic acid and dried by means of quicklime, is passed over it. For the first eight minutes the gas is eagerly absorbed by the baryta. After it has begun to escape from the farther end of the tube (to which a gas delivery-tube passing under water is fitted), the stream is still kept up for the space of ten or fifteen minutes. The peroxide of barium obtained by this process is, after cooling, preserved in a bottle. In the next place, 200 grms. of water are mixed with as much hydrochloric acid as will neutralise about 15 grms. of baryta. Into this liquid, contained in a cylinder, or better, in a dish of silver or platinum kept cool by surrounding it with ice, 12 grms. of peroxide of barium, slightly moistened and rubbed up in an agate mortar, are introduced by means of a wooden spatula: on agitating or stirring the liquid with the pestle, the whole dissolves completely and without effervescence. The baryta is next precipitated by sulphuric acid, added drop by drop till slightly in excess: the presence of an excess of the acid may be known by the sulphate of barium falling down more quickly than before. 12 grms. more of the peroxide are then dissolved in the same liquid, and likewise precipitated by sulphuric acid. The liquid, which now contains hydrochloric acid, sulphuric acid, a large quantity of water, and a small quantity of peroxide of hydrogen, is next separated by filtration from the sulphate of barium, the precipitate washed with a little water, and the last wash-water retained for future washings. The filtrate is again mixed, as above, twice with peroxide of barium, and twice with sulphuric acid. The filtration is then repeated, and the process continued in the same way, till 90 or 100 grms. of the peroxide are consumed. The liquid thus obtained would, on decomposition, yield from 25 to 30 measures of oxygen gas. To separate silica, alumina, sesquioxide of iron, sesquioxide of manganese, &c., which proceed from the porcelain retort in which the nitrate of baryta was ignited, the liquid is mixed with concentrated solution of phosphoric acid (2 or 3 pts. of phosphoric acid to 100 pts. of peroxide of barium)—then surrounded with ice, and supersaturated with pounded peroxide of barium: silica and the phosphates of iron, manganese, and aluminium then separate rapidly in flakes, and must be separated from the liquid by filtration through linen, and if necessary through paper. The presence of a large quantity of sulphate of barium renders the filtration difficult. (If no phosphoric acid were present, the sesquioxides of iron and manganese would fall down by themselves, and give rise to a rapid evolution of oxygen gas; but when they are mixed with phosphoric acid, they do not produce this effect.) Should the liquid still contain portions of these oxides, they must be separated by the addition of a slight excess of baryta-water; whereupon, the liquid must be immediately and rapidly filtered through several filters at once, and the filters squeezed between linen to get all out. The whole of the baryta must then be separated by carefully adding sulphuric acid in very slight excess, and filtering. The filtrate now contains nothing but water, peroxide of hydrogen, hydrochloric acid, and a very little sulphuric acid. To separate the hydrochloric acid, the liquid is surrounded with ice, and mixed with sulphate of silver. In the first place, sulphate of silver, obtained by heating nitrate of silver in contact with oil of vitriol in a platinum crucible, is introduced in the form of powder into the liquid—the whole being constantly stirred till the liquid becomes clear, a sign that the hydrochloric acid is wholly or nearly precipitated. Any hydrochloric acid that may still remain must be separated by cautiously adding more sulphate of silver. If the latter has been added in excess, it must be precipitated by carefully dropping in a dilute solution of chloride of barium. The liquid should contain neither hydrochloric acid nor silver, and should therefore give no precipitate either with solution of silver or with hydrochloric acid. The chloride of silver is separated by filtration and pressure, any portion of liquid which comes through turbid being filtered over again. To remove the sulphuric acid also, and obtain a pure mixture of water and peroxide of hydrogen, the liquid is placed in a glass mortar surrounded with ice, and rubbed up with slaked baryta previously pounded and diffused through water: the baryta is added till the sulphuric acid is very nearly saturated. The liquid is then filtered, the filter pressed between linen, and baryta-water added in slight excess. this often occasions the precipitation of oxide of iron and oxide of manganese, as well as sulphate of barium; hence the filtration

Digitized by Google

must be rapidly performed. The excess of baryta is removed by cautiously adding dilute sulphuric acid, so that there may be rather a very slight excess of the acid than of the baryta. The whole of the sulphuric acid may likewise be removed by means of carbonate of barium obtained in a finely-divided state by precipitation, instead of by slaked baryta and baryta-water. Finally, to separate the whole or nearly the whole of the water, the vessel containing the liquid is placed in a dish containing oil of vitriol, and the whole placed under a receiver of the air-pump: the water then evaporates before the peroxide of hydrogen. The fluid is agitated from time to time. If it should deposit flakes of silica, which give rise to the escape of oxygen gas, it must be decanted off from them by means of a siphon: if it should evolve oxygen—which it will do as soon as it is so far concentrated as to contain about 250 times its volume of oxygen—two or three drops of sulphuric acid must be added to it. The concentration must be stopped after a few days, when the liquid is brought to such a state that when decomposed it would evolve 475 volumes of oxygen gas; for this residue, if left longer in vacuo, would evaporate as a whole. The peroxide of hydrogen must be kept in long glass tubes closed with stoppers and surrounded with ice; but, even under these circumstances, it decomposes slowly and evolves oxygen gas. (Thénard.)

2. Peroxide of barium is decomposed by hydrated hydrofluoric acid or solution of hydrofluosilicic acid, the whole being kept constantly cool: in this case, insoluble fluoride of barium or double fluoride of silicium and barium separates at once. As soon as sufficient quantities of acid and peroxide of barium have been mixed, the peroxide of hydrogen, still containing a large quantity of water, is filtered from the precipitate and concentrated in vacuo over oil of vitriol. (Pelouze, *Ber. Lehrb.* i. 411.)

Properties.—Colourless transparent liquid, of specific gravity 1·452; it does not freeze at −30°; evaporates in vacuo at ordinary temperatures without decomposition, though much less readily than water; does not redden litmus, but gradually bleaches both litmus and turmeric paper; has a harsh, bitter taste, similar to that of tartar-emetic; whitens the tongue and thickens the saliva; when placed upon the hand, it instantly turns the cuticle white, and after a time produces violent itching. (Thénard.)

Peroxide of hydrogen is miscible in all proportions with *water*, part of the water freezing out on exposure to cold. A solution containing eight times its own volume of oxygen gas begins to evolve gas at 50°, and subsequently gets into a state of violent ebullition, and when this has ceased, nothing is left but water. The peroxide likewise unites with *acids*, *e.g.* phosphoric, sulphuric, hydrochloric, nitric acid, &c., forming mixtures in which it is less easily decomposible than when alone.

It is doubtful whether peroxide of hydrogen has ever been obtained quite free from water. Thénard, however, found in a specimen prepared as above described, 6·02 per cent. hydrogen, and 93·98 oxygen, the formula HO requiring 5·88 H, and 94·12 O.

Decompositions.—The second atom of oxygen is retained by the hydrogen very loosely. Under various, and often enigmatical circumstances, it separates from the water in the form of gas, the volume of which at 14° and 0·76^{m}. bar. (29·8 inches) amounts to 475 times that of the liquid. The gas often escapes with such rapidity as to produce violent effervescence, and even explosion. Great heat is also developed, and when the experiment is made in the dark, even light is apparent.

The several modes of decomposition are as follows:—

1. In the circuit of the voltaic battery, peroxide of hydrogen, like water, is gradually resolved into hydrogen at the negative and oxygen at the positive pole—only that the proportion of oxygen is greater than in the decomposition of water. (Thénard.)

2. By a certain elevation of temperature. At freezing temperatures, peroxide of hydrogen is but very slowly decomposed; at ordinary temperatures, it merely evolves a bubble of oxygen now and then, the decomposition not being complete for months; at 20° the escape of gas becomes more perceptible. By suddenly raising the temperature to 100°, this gradual escape of gas may be converted into a kind of explosion. Finally, there remains behind nothing but pure water. Sunshine does not appear to accelerate the decomposition at ordinary temperatures. (Thénard.)

3. By contact with certain substances, which either remain unaltered, or take up part of the oxygen of the peroxide, or on the contrary themselves evolve oxygen.—The rapidity with which these substances induce the separation of oxygen from the peroxide depends partly on their chemical nature, partly on the minuteness of their mechanical division: the further this is carried, the more rapid is the action. (Thénard.)

a. Peroxide of hydrogen, whether pure or in aqueous solution, acts as a powerful oxidising agent. It converts arsenious acid into arsenic acid, sulphurous acid into sulphuric acid, sulphide of lead into sulphate of lead, and the hydrated protoxides of manganese, iron and cobalt, into the peroxide and sesquioxides respectively. The protoxides of barium, strontium, and calcium are transformed into the corresponding

Digitized by Google

peroxides, which, being insoluble, are precipitated. The concentrated solution of p oxide of hydrogen acts with great violence upon certain of the elements, seleniu arsenic, molybdenum, chromium, &c., converting them at once into their highest oxid

b. Certain bodies, among which are included charcoal, many metals, and so metallic oxides, induce, by their mere contact, a more or less violent decomposition the peroxide into water and oxygen, without themselves undergoing any change: go platinum, and silver, particularly when in the precipitated or spongy state, act m violently, and cause a great disengagement of heat. A slightly acid solution of t peroxide is less amenable to the action of these agents than is the pure aqueous so tion; alkalis on the other hand facilitate the decomposition. The action of the abo mentioned bodies in causing the decomposition of the peroxide is termed catalyt Its nature, however, is not at present understood.

c. But the most remarkable circumstance connected with peroxide of hydrogen is property of acting as a reducing agent. When peroxide of hydrogen, or its analog peroxide of barium, is added to any one of the following substances, namely, the p toxides of silver or mercury, the peroxides of manganese or lead, the chromic, perma ganic, and ferricyanic acids, or their salts, not only is oxygen evolved from t peroxide of hydrogen, but also from the other oxidised body. Several of these reacti were noticed by Thénard in 1818, but they were first minutely examined a explained by Brodie in 1850 (Phil. Trans. 1850, p. 759; Chem. Soc. Qu. J. iv. 19 further, Chem. Soc. Qu. J. vii. 304). In accordance with his views, it seems that t second atom of oxygen in the peroxides of hydrogen and barium is not merely retai in an unstable state of combination, but that it is, by association with the oxide of electro-positive element, like hydrogen or barium, thrown into a polar state, oppos to the polar state of the oxygen in unstable protoxides, and to that of the loos combined oxygen in the more or less chlorous peroxides. Hence when the perox of hydrogen or barium is brought into relation with one or other of these oxygeni compounds, the two oppositely polarised oxygens unite with one another, as indica in the following formulæ:—

$$\overset{+}{\mathrm{Mn}}\overline{\mathrm{OO}} + \overset{+}{\mathrm{H}^2}\overline{\mathrm{OO}} = \overset{+}{\mathrm{Mn}}\overline{\mathrm{O}} + \overset{+}{\mathrm{H}^2}\overline{\mathrm{O}} + \overset{+}{\mathrm{O}}\overline{\mathrm{O}}$$

$$\overset{+}{\mathrm{Ag}}\overline{\mathrm{Ag}}\overline{\mathrm{O}} + \overset{+}{\mathrm{H}^2}\overline{\mathrm{OO}} = \overset{+}{\mathrm{Ag}}\overline{\mathrm{Ag}} + \overset{+}{\mathrm{H}^2}\overline{\mathrm{O}} + \overset{+}{\mathrm{O}}\overline{\mathrm{O}}$$

$$\overset{+}{\mathrm{Cr}^2}\overline{\mathrm{O}^3}\overline{\mathrm{O}^3} + \overset{+}{\mathrm{H}^6}\overline{\mathrm{O}^3}\overline{\mathrm{O}^3} = \overset{+}{\mathrm{Cr}^2}\overline{\mathrm{O}^3} + 3\overset{+}{\mathrm{H}^2}\overline{\mathrm{O}} + 3\overset{+}{\mathrm{O}}\overline{\mathrm{O}}$$

$$\overline{\mathrm{I}^2} + \overset{+}{\mathrm{H}^2}\overline{\mathrm{OO}} = 2\overset{+}{\mathrm{H}}\overline{\mathrm{I}} + \overset{+}{\mathrm{O}}\overline{\mathrm{O}}$$

Brodie has shown that, in the third and fourth reactions, the amounts of oxygen free correspond exactly with the above expressions. In the other two reactions, so additional oxygen is set free catalytically, from the decomposition of the peroxide *per se*. For finely-divided metallic silver has the property of decomposing peroxide hydrogen catalytically, whence the oxygen liberated according to the second equati has not been found to constitute more than 49, instead of 50, per cent. of the to quantity of oxygen evolved. It is observable that in no case can the oxygen from t peroxide constitute less than one-half of the total oxygen liberated. The above actions are perfectly comparable with admitted reactions showing the formation hydrogen and the alcohol-radicles (see CHEMICAL AFFINITY i. 857), for example:—

$$\overset{+}{\mathrm{Cu}^2}\overline{\mathrm{H}^2} + 2\overset{+}{\mathrm{H}}\overline{\mathrm{Cl}} = \overset{+}{\mathrm{Cu}^2}\overline{\mathrm{Cl}^2} + 2\overset{+}{\mathrm{H}}\overline{\mathrm{H}}.$$

$$\overset{+}{\mathrm{Zn}}(\overline{\mathrm{C}^2\mathrm{H}^3})^2 + 2(\overset{+}{\mathrm{C}^2}\overline{\mathrm{H}^3})\overline{\mathrm{I}} = \overset{+}{\mathrm{Zn}}\overline{\mathrm{I}^2} + 2(\overset{+}{\mathrm{C}^2}\overline{\mathrm{H}^3})(\overline{\mathrm{C}^2\mathrm{H}^3}).$$

Schönbein, apparently unaware of Brodie's researches, has recently drawn attenti to the phenomena of deoxidation effected by the peroxides of hydrogen and bariu and has shown that ozone is rendered inactive by them. He regards ozone as perm nently negative oxygen, $\overline{\mathrm{O}}$, which can form ozonides of silver, of manganous oxide, & and, in the above reaction, is neutralised by the permanently positive oxygen *antozone*, $\overline{\mathrm{O}}$, of the peroxide of hydrogen; whereas, according to Brodie, the polarity the oxygen depends upon the nature of the body with which it is associated, and manifested only at the instant of its disassociation. (Schönbein, Verhandl. d. natu Gesellsch. in Basel. ii. 113, 463, 472; Ann. Ch. Pharm. cviii. 157; J. pr. Chem. lxx 257, 263; lxxx. 266, 275; lxxxi. 1; lxxxiii. 86; Jahresber. 1858, p. 58; 1859, p. 6 1860, p. 54; 1862, p. 96.)

Schönbein has confirmed the observations of Meidinger and others, that peroxide hydrogen may sometimes be detected in water which has undergone electrolysis. seems also to have shown that traces of peroxide of hydrogen are produced in ma

Digitized by Google

cases of slow oxidation occurring in the presence of moisture; for example, those of phosphorus, ether, zinc, &c. This production of peroxide of hydrogen he considers to be correlative of the other oxidation. Thus when moist zinc-filings are oxidised by exposure to air, a quantity of peroxide of hydrogen, which may be dissolved out by water and submitted to chemical tests, is formed, according to the following equation:

$$\overset{+}{Zn}^2 + 2\overset{+}{H}^2\overset{-}{O} + 2\overset{+}{H}^2\overset{-}{O} + 2\overset{+}{O}\overset{-}{O} = \overset{+}{Zn}\overset{+}{H}^2\overset{-}{O}^2 + \overset{+}{Zn}\overset{+}{H}^2\overset{-}{O}^2 + 2\overset{+}{H}^2\overset{-}{O}\overset{+}{O}.$$

Peroxide of hydrogen, even in a very dilute state, may be recognised either by its oxidising or by its reducing properties. Thus it decolorises a solution of indigo, especially in the presence of sulphate of iron, which apparently serves to convey the oxygen from the peroxide to the indigo; and similarly it liberates iodine from a solution of iodide of potassium, starch, and sulphate of iron. On the other hand, it decolorises a solution of permanganate of potassium by reduction, and causes a blue precipitate in a solution containing sesquichloride of iron and ferricyanide of potassium. It eventually reduces chromic acid to the state of chromic hydrate, but its first action is to produce, by oxidation, a very unstable perchromic acid. This compound, which has a deep blue colour, is readily soluble in ether, and its ethereal solution has a certain degree of stability; so that the presence of peroxide of hydrogen in any liquid may be ascertained by mixing it with ether, and then adding a few drops of a solution of chromic acid, whereby the ether assumes a bright blue colour.

The compound radicle, peroxide of hydrogen HO, is equivalent to the simple radicle chlorine Cl, and in a great number of reactions is exchangeable for chlorine and its congeners. One of the most generally useful modes of oxygenating different compounds consists in first substituting a halogen in exchange for hydrogen, and then, by means of water, substituting peroxide of hydrogen in exchange for the halogen. Thus, by the action of bromine upon acetic acid, we obtain bromacetic acid:—

$$C^2H^4O^2 + Br^2 = C^2H^3BrO^2 + HBr.$$

Then, by the action of water upon bromacetic acid, we obtain glycollic, or oxyacetic acid:—

$$C^2H^3BrO^2 + H.HO = C^2H^3(HO)O^2, \text{ or } C^2H^4O^3 + HBr.$$

(*Odling's Manual of Chemistry*, p. 124.)

Trioxide of Hydrogen. H^2O^3.—This, according to Baumert (Pogg. Ann. lxxxix. 38), is the composition of Ozone (*q. v.*)

HYDROGEN, PHOSPHIDES OF. Three of these compounds are known, viz. phosphoretted hydrogen gas, PH^3, liquid phosphide of hydrogen, PH^2, and the solid phosphide, P^8H.

1. **Phosphoretted Hydrogen** or **Phosphamine.** PH^3.—This gas, the analogue of ammonia, is produced by the spontaneous decomposition of phosphorised organic bodies, decaying fish for example. Its natural evolution appears to be the cause of *ignes fatui* and similar luminous appearances. The gas is also liberated in many chemical reactions, but it is very difficult to obtain pure, being always mixed with a greater or lesser proportion of free hydrogen, and frequently with the vapour of liquid phosphide of hydrogen, which renders it spontaneously inflammable, a property which it does not possess when free from the liquid phosphide. The spontaneously inflammable gas was discovered in 1789 by Gengembre (Crell. Ann. i. 450), and the non-spontaneously inflammable gas by Davy some years later.

Production of the spontaneously inflammable gas. 1. The compounds of phosphorus with the alkali-metals are resolved, in contact with water, into an alkaline hypophosphite and phosphoretted hydrogen. An impure phosphide of calcium is generally used for the purpose, prepared by heating phosphorus with lime (i. 719). When it is thrown into water, spontaneously inflammable phosphoretted hydrogen is slowly liberated, and the bubbles of gas, as they reach the surface, take fire, burn with a highly luminous flame, and produce thick clouds of white smoke, which, in a quiet atmosphere, ascend in the form of successive gradually expanding rings.

2. Phosphide of zinc, tin, or iron, with aqueous sulphuric or hydrochloric acid, yields a metallic sulphate or chloride and phosphoretted hydrogen gas.

3. Phosphorus heated in an aqueous solution of a fixed alkali, yields phosphoretted hydrogen gas, together with a hypophosphite and phosphate of the alkali-metal. Such an action is exerted by potash, soda, lithia, baryta, strontia, and lime, and, according to Raymond, by oxide of zinc and protoxide of iron. The primary decomposition yields phosphoretted hydrogen and hypophosphite; thus with lime-water:—

$$3CaH^2O^2 + P^8 + 6H^2O = 3CaH^4P^2O^4 + 2PH^3$$

Hydrate of calcium. Hypophosphite of calcium.

Digitized by Google

from the very beginning of the action, the phosphoretted hydrogen gas is mixed
n more or less free hydrogen, and there is likewise a certain quantity of phosphate
duced; and as the boiling is continued and the solution becomes more concentrated,
quantity of hydrogen gas continually increases, because a greater and greater
ntity of the alkaline hypophosphite is resolved, by boiling in the alkaline liquid
hydrogen and an alkaline phosphate, *e.g.*:

$$\underset{\text{Hypophosphite of potassium.}}{KH^2PO^2} + 2KHO = \underset{\text{Phosphate of potassium.}}{K^3PO^4} + H^4.$$

s secondary decomposition takes place especially with the hypophosphites of the
e alkali-metals; hence solutions of the alkaline earths are best adapted for the
paration of pure phosphoretted hydrogen.
. When hypophosphites are heated, phosphoretted hydrogen is evolved, generally of
more inflammable, more rarely of the less inflammable variety, mixed with a
ain quantity of vapour of phosphorus and free hydrogen gas. (H. Rose.)
The non-spontaneously inflammable gas is produced—1. When hypophosphorous or
sphorous acid is heated, these acids being then resolved into phosphoric acid and
sphoretted hydrogen, which may be collected over water:

$$\underset{\text{Hypophosphorous acid.}}{2H^3PO^2} = PH^3 + H^3PO^4.$$

$$\underset{\text{Phosphorous acid.}}{4H^3PO^3} = PH^3 + 3H^3PO^4.$$

ording to Dumas and H. Rose, the first portions of gas evolved by this process are
e, but the later portions contain a considerable quantity of free hydrogen. The
sphorous acid should be gently heated in a flask of hard glass, as when softer glass
sed, a phosphite of alkali-metal is frequently formed, which is decomposed by the
t and yields free hydrogen. The mixture of phosphorous and phosphoric acids,
metimes called *phosphatic acid*, which is produced when phosphorus is left to oxidise
wly in moist air, may be used for the purpose. By the application of a stronger
t, hypophosphites, as well as hypophosphorus itself, yield phosphoretted hydrogen,
the gas produced from the salts is usually spontaneously inflammable and mixed
h free hydrogen.—2. When zinc or iron is dissolved in aqueous phosphorous acid,
inc in a mixture of aqueous phosphorous acid and sulphuric acid, or when phos-
ric acid is deoxidised by potassium or sodium (Wöhler).—3. When phosphorus is
led with hydrate of potassium and alcohol, the non-inflammable gas is evolved, mixed
h hydrogen gas and alcohol vapour, and there remains hypophosphite of potassium
a small quantity of phosphate, together with excess of potash (H. Rose).—4. When
sphide of calcium is decomposed by concentrated hydrochloric acid (Dumas).—
Phosphorus, under the influence of light, decomposes water, producing phosphoric
de [? red phosphorus] and phosphoretted hydrogen gas, which remains dissolved in
water.

Spontaneously inflammable phosphoretted hydrogen may be freed from the com-
und PH^3, and rendered non-inflammable, by passing it through a freezing mixture of
and salt; but according to Graham, the addition of a minute quantity of nitric
de gas will confer on it the property of spontaneous inflammability [? by oxidising
mall quantity of it to PH^2]. It is also deprived of its spontaneous inflammability
exposure to sunlight, by contact with charcoal and other pulverulent bodies, and by
nixture with the vapours of ethylic chloride, ethylic oxide, alcohol, turpentine, &c.
Properties. Phosphoretted hydrogen is a colourless gas of specific gravity 1·214
erred to air, or 17·25 referred to hydrogen (Dumas); by calculation for a condensation
2 volumes it is $\frac{31 + 3}{2} = 17$. It is liquefiable, but has not yet been solidified
98). It smells like stinking fish, or rather the fish in a state of decomposition have
odour of the gas, since they evolve it. It is sparingly soluble in water, more so in
ohol, ether, and volatile oils. Neither the gas nor its solutions have any action upon
e or red litmus paper.
Decompositions.—1. When a series of *electric sparks* is passed through the gas, two
umes of it are converted, with deposition of phosphorus, into three volumes of hy-
gen.—2. Most *metals* heated in the gas combine with the phosphorus, and liberate
hydrogen.—3. Phosphoretted hydrogen is very inflammable, burning with a
lliant flame and evolving a white smoke of phosphoric acid. A mixture of the non-
ntaneously inflammable gas and *oxygen* standing over water is gradually absorbed,
h production of phosphorous acid. The mixture of the two gases, though changing
y gradually at ordinary pressures, undergoes, when suddenly rarefied, an instan-
eous decomposition, attended with violent explosion.—4. Phosphoretted hydrogen

Digitized by Google

quickly reduces many oxidised bodies, *e.g. nitric oxide, nitric acid, sulphurous anhydride* and *sulphuric acid*. It is completely absorbed by solutions of *hypochlorous acid* and the alkaline hypochlorites.—*5.* It precipitates the solutions of many *metallic salts* those of *lead* very slowly, those of *copper* more quickly, and those of the *noble metals* most quickly of all. The precipitates, save those produced with mercury-salts, are black or dark-coloured. They consist of metallic phosphide, as in the case of copper; of mixed phosphide and metallic salt, as in the case of mercury; or of reduced metal, as in the case of silver and gold. Solution of sulphate of copper is often used for estimating the proportion of free hydrogen in ordinary phosphoretted hydrogen, by observing the quantity of gas which it leaves unabsorbed.

6. Chlorine, bromine, and *iodine* decompose phosphoretted hydrogen, abstracting its hydrogen. If in excess, they also combine with its phosphorus to form the respective chlorides, bromides, and iodides, or their products of decomposition with water. When bubbles of phosphoretted hydrogen are introduced into a receiver of chlorine, they inflame with a sharp explosion, producing hydrochloric acid and pentachloride of phosphorus. Many metallic chlorides also, when gently heated in phosphoretted hydrogen, produce hydrochloric acid gas—the volume of which is three times as great as that of the phosphoretted hydrogen—and a metallic phosphide; or else hydrochloric acid, free phosphorus and free metal.—*6. Sulphur* heated in phosphoretted hydrogen forms sulphide of hydrogen and sulphide of phosphorus.

Phosphoretted hydrogen, though devoid of any alkaline reaction, is in other respects closely analogous to ammonia; hence it is called phosphamine. Thus it unites directly with *hydriodic acid* to form the hydriodate of phosphamine, $PH^3.HI$, or iodide of phosphonium, PH^4I, and a corresponding compound with *hydrobromic acid*. Moreover, like ammonia, phosphamine unites with the perchlorides of many metals, forming white saline bodies of similar constitution to the ammonio-chlorides.

Hydriodate of Phosphamine may be obtained by the direct combination of the two gases, or by adding a little water to equal atomic proportions of iodine, ground up with pounded glass, and phosphorus cut up into small pieces. Vapours of hydriodate of phosphamine mixed with hydriodic acid are immediately given off, the former condensing as a crystalline deposit. A better mode of preparation is, however, that given by Hofmann, which consists in gently heating iodine in a current of dry phosphoretted hydrogen gas:

$$4PH^3 + I^4 = PI^2 + 3H^4PI.$$

The salt crystallises in cubes, which fuse when moderately heated, and out of access of air, may be sublimed without change. They are deliquescent and are decomposed by water into hydriodic acid and phosphamine.

Hydrobromate of Phosphamine, $PH^3.HBr$ or PH^4Br, is also obtained by direct combination, or it may be prepared by introducing bromide of silicon, together with a little water, into a jar of phosphoretted hydrogen (Serullas). It crystallises in cubes, sometimes transparent, sometimes opaque; boils at about 30°. Vapour-density, obs. = 1·906; calc. (2 vol.) = 3·98; hence this compound affords an example of anomalous vapour-density, probably arising from disassociation (i. 469; ii. 816).

Derivatives of Phosphamine.—The three atoms of hydrogen, like those of ammonia, in phosphamine, may be replaced by metals or organic radicles, *e.g. tricupric phosphide,* $P^2(Cu'')^3$; *tricuprous phosphide,* $P^2(Cu^2)^3$; *triethylphosphine,* $P(C^2H^5)^3$. The metallic phosphamines are obtained by passing phosphoretted hydrogen gas over the heated metals or their oxides, or into solutions of the respective salts, or by treating the metals directly with phosphorus. (See Phosphides.)

The organic derivatives of phosphamine constitute a more important class of compounds, exactly analogous to the tertiary monamines (i. 175). Phosphorus-bases analogous to the primary and secondary monamines have not yet been obtained. The tertiary phosphines are obtained by decomposing the zinc-compounds of the alcohol-radicles with trichloride of phosphorus, *e.g.*:

$$\underset{\text{Zinc-ethyl.}}{3Zn(C^2H^5)^2} + 2PCl^5 = 3ZnCl^2 + \underset{\substack{\text{Triethyl-}\\\text{phosphine.}}}{2P(C^2H^5)^3}.$$

They are volatile strongly basic compounds, which unite readily with acids, forming crystalline salts, analogous to those of triethylamine, &c. Triethylphosphine (like triethylamine) unites directly with iodide of ethyl, forming the iodide of tetrethylphosphonium, $P(C^2H^5)^4I$, from which, by the action of moist oxide of silver, the hydrate of tetrethylphosphonium, $P(C^2H^5)^4HO$, may be obtained. (See Phosphorus-bases.)

Liquid Phosphide of Hydrogen. This compound, which communicates spontaneous inflammability to phosphoretted hydrogen gas, was discovered by Paul Thénard (Ann. Ch. Phys. [3] xiv. *5*), and regarded by him as PH^2. By some chemists, however, it is supposed to contain oxygen as well as hydrogen, and to

Digitized by Google

constitute the hydrogen representative of oxychloride of phosphorus, nam
It is produced, together with spontaneously inflammable phosphoretted hyd
by the action of water on phosphide of calcium (i. 719):

$$5PCa + 5H^2O = 5CaO + 5PH^2 \text{ (P. Thénard),}$$

and may be separated by passing the gas through a U-tube cooled by a freezi

parts which have been drawn out closed by the blowpipe. The apparatus
arranged, the bottle is three parts filled with water and placed in a water-b
to between 60° and 70°; the last-mentioned tube is closed; and a few drop
phide of calcium are thrown through the middle one into the bottle. The g
takes fire, and drives out the air through the safety-tube. The U-tube is
opened, and from 400 to 600 grains of phosphide of calcium gradually intro
the bottle: in a few minutes, oily drops of liquid are seen to collect in the
tube nearest to the bottle. The process must be stopped after 15 or 2
because water condenses in the tube, together with the phosphide of hyd
often stops it. The tube is now to be sealed at the narrowed neck nea
extremity, then removed from the bottle, and held by the finger (cov
caoutchouc to save the operator from being burnt) in such a position
remaining gas may escape; it is then warmed by the hand to cause the
liquid which have been separated by particles of ice to run together, and ag
in the freezing mixture to solidify the water, and prevent it running back.
effected, the liquid is made to flow towards the sealed end of the tube, and
neck of the tube is closed by the blow-pipe. A well-conducted operation yi
30 grains of liquid.

Liquid phosphide of hydrogen is colourless and does not solidify at −20°
40°, it appears to volatilise and to be decomposed at the same time; ref
strongly. It is insoluble in water. Alcohol and oil of turpentine appear t
it, but it quickly decomposes in the solution. It burns spontaneously in the
an intensely bright white flame, and produces dense white fumes. It com
spontaneous inflammability to 500 times its weight of phosphoretted hyd
All combustible gases are rendered spontaneously inflammable by admixture
phosphide of hydrogen.

By the action of light it is resolved into solid and gaseous phosphide of
$5PH^2 = P^2H + 3PH^3$. It is also decomposed, like peroxide of hydrogen,
with various substances. An indefinite quantity of liquid phosphide of hyd
be decomposed by a cubic centimetre of hydrochloric acid gas.

Solid Phosphide of Hydrogen. P^2H?—When spontaneously in
phoretted hydrogen is exposed to sunshine, a solid yellowish compou
posited on the sides of the glass, the gas at the same time losing its propert
taneous inflammability (Leverrier, Ann. Ch. Phys. lx. 175). The same
pound is obtained in larger quantity by treating liquid phosphide of hyd
hydrochloric acid, or by dissolving phosphide of calcium in strong hydroc
the liquid phosphide being then resolved into the solid and gaseous phosp
above). Hence spontaneously inflammable phosphoretted hydrogen passe
aqueous hydrochloric acid loses its spontaneous inflammability and yields a
solid phosphide.

This compound is insoluble in water and in alcohol. It dissolves in wa
with liberation of non-spontaneously inflammable phosphoretted hydrogen.
fire at about 150°. (P. Thénard, *loc. cit.*)

HYDROGEN, SELENIDE OF. H^2Se. *Selenhydric* or *Hydrose*
Selenietted Hydrogen.—A gaseous compound analogous to sulphydric acid
by the action of dilute hydrochloric or sulphuric acid on selenide of potassiu
other metals. It is colourless and inflammable, soluble in water, and cann
preserved over mercury. It has a most offensive, acrid odour, impairing o
stroying the sense of smell for several hours, and producing inflammation of th
aqueous solution absorbs oxygen from the air, and deposits selenium. It ha
taste, a slight acid reaction, and gives with the solutions of most metals, p
consisting of metallic selenides, those of manganese, zinc, and cerium b
coloured, the remainder brown or black. (Berzelius.)

HYDROGEN, SULPHIDES OF. Sulphur unites with hydrogen in two proportions, forming the protosulphide, H^2S; and the persulphide, probably HS or H^2S^2.

Protosulphide of Hydrogen. H^2S. *Sulphydric acid. Hydrosulphuric acid. Hydrothionic acid. Sulphuretted hydrogen.*—This compound may be formed in small quantity by burning sulphur-vapour in hydrogen gas, or hydrogen gas in sulphur-vapour, precisely as its analogue, water, is produced under similar circumstances from oxygen and hydrogen.

The gas is ordinarily prepared by the action of an acid—sulphuric or hydrochloric for instance—upon a metallic sulphide, usually that of iron or antimony. Dilute sulphuric acid acts readily upon sulphide of iron, producing, even in the cold, a rapid effervescence of sulphydric acid:

$$FeS + H^2SO^4 = H^2S + FeSO^4.$$

Inasmuch as sulphide of iron is an artificial product, nearly always containing an excess of metallic iron in admixture, the sulphydric acid obtained from it is generally contaminated with free hydrogen; but the native crystalline trisulphide of antimony, being a normal sulphide, when acted upon by boiling hydrochloric acid, yields the gas in question in a very pure state, thus:

$$Sb^2S^3 + 6HCl = 3H^2S + 2SbCl^3.$$

The sulphydric acid obtained from either of these sources may be passed through a small quantity of water to wash it, and over chloride of calcium to render it dry. It may be collected in the gaseous state over mercury, or absorbed at once into water, in which it is very soluble.

Sulphydric acid, more frequently sulphydrate of ammonia, results from the spontaneous decomposition of sulphuretted organic compounds; also from treating non-sulphuretted organic compounds with sulphur. Reinsch recommends a laboratory process for obtaining pure sulphydric acid, by heating in a glass flask a mixture of equal parts of sulphur and suet.

Sulphydric acid occurs naturally, and is not unfrequently evolved from fumaroles and volcanoes. It exists to a considerable extent in certain mineral waters known as hepatic waters, those of Harrogate, for instance. It is also produced spontaneously in many waters charged with organic matter and sulphates, usually sulphate of calcium.

Properties.—At ordinary temperatures and pressures, sulphydric acid is gaseous. It may be obtained in the liquid state by generating it in one limb of a sealed tube, from sulphuric acid and sulphide of iron freed from metallic iron, and condensing it in the other limb, which should be immersed in a freezing mixture, that of ice and salt being sufficient for the purpose; or liquid persulphide of hydrogen may be gently heated in one limb of a bent sealed tube, when it breaks up into sulphur, which remains, and sulphydric acid, which may be condensed in the other limb kept cool for the purpose. By the powerful refrigeration resulting from the evaporation *in vacuo* of a mixture of solid carbonic anhydride and ether, it may be solidified. Solid sulphydric acid, or sulphur-ice, is a white transparent mass which melts at $-85{\cdot}5°$. Liquid sulphydric acid is a colourless transparent fluid, remarkable for its extreme thinness or mobility. Its specific gravity is 0·9 compared with that of water as 1. Sulphydric acid gas is transparent and colourless. Its density is somewhat greater than that of atmospheric air, being 1·1781 referred to air, or 17 referred to hydrogen, as unity. It is characterised by an offensive odour resembling that of rotten eggs, the smell of which indeed is due to the evolution of this gas, or of its compound with ammonia. In the concentrated state it cannot be breathed with impunity, and even when much diluted it frequently gives rise to nausea and vertigo. An atmosphere containing $\frac{1}{10}$ per cent. of this gas proves fatal to the lower animals.

Sulphydric acid is readily inflammable. It burns with a bluish flame, forming sulphurous acid, and frequently deposits free sulphur from the imperfect access of oxygen. Most *metals* when heated in the gas absorb the sulphur and leave the hydrogen. *Cadmium* or *tin* is generally used for the purpose: $Cd^2 + H^2S = Cd^2S + H^2$. The bulk of the resulting hydrogen is equal to that of the original sulphydric acid; or, in other words, two volumes of sulphydric acid, H^2S, when acted on by metal, leave two volumes of hydrogen. Sulphydric acid in the gaseous state, or dissolved in water, is decomposed by *chlorine*, *bromine*, and *iodine*, with liberation of sulphur and formation of hydrochloric, hydrobromic, and hydriodic acids respectively. In a similar manner it is decomposed, with liberation of sulphur, by nearly all *oxidising agents;* and even *sulphurous acid*, which usually acts as a deoxygenant by absorbing oxygen, acts in this case as an oxygenant by affording oxygen:

$$2H^2S + SO^2 = 2H^2O + S^3.$$

In some cases, however, a peculiar sulphur-acid, the pentathionic, is formed in addition, thus

$$5H^2S + 5SO^2 = 4H^2O + H^2S^5O^6 + S^3.$$

Digitized by Google

A saturated aqueous solution of sulphydric acid contains about three times its volume of the gas. It is a clear colourless liquid, having a slight acid reaction, and the smell and taste of the gas. It is gradually decomposed by exposure to air, its hydrogen being oxidised into water and its sulphur set free. Sulphydric acid when burnt yields sulphurous acid, as we have seen; but moist sulphydric acid, mixed with air or oxygen, and exposed to a moderately warm temperature, from 40° to 90°, is converted into sulphuric acid.

Sulphydric acid, like water, is capable of giving up the half or the whole of its hydrogen in exchange for a metal, the resulting compound being a sulphydrate or a sulphide, according as 1 or 2 at. H are thus replaced; *e. g. sulphydrate of barium*, BaHS; *sulphide of barium*, Ba^2S. It is only the alkali-metals and alkaline-earth-metals that appear to be capable of forming definite sulphydrates, all of which are soluble in water and crystallisable. The heavy metals form insoluble sulphides, which may be derived from a single or a multiple molecule of sulphydric acid, just as the corresponding oxides are derived from a single or multiple molecule of water: *e. g. sulphide of silver*, Ag^2S; *mercuric sulphide*, Hg^2S or $Hg''S$; *trisulphide of antimony*, Sb^2S^3, &c. (See SULPHIDES and SULPHYDRATES.)

The sulphides of the heavy metals are precipitated from solution of metallic salts by sulphydric acid or an alkaline sulphide or sulphydrate:

$CuSO^4$	+	H^2S	=	H^2SO^4	+	CuS.
$2SbCl^3$	+	$3H^2S$	=	6HCl	+	Sb^2S^3.
$FeSO^4$	+	$NH^4.H.S$	=	$NH^4.H.SO^4$	+	FeS.

Some metals are precipitated in this manner from their acidified solutions by sulphydric acid gas or its aqueous solution; others only from neutral or nearly neutral solutions, by an alkaline sulphide or sulphydrate, in some cases as sulphides (nickel, cobalt, manganese, zinc, uranium), in others as hydrates (chromium, and the metals of the earths proper); and and lastly, there are some metals, namely those of the alkalis and alkaline earths, which are not precipitated either by sulphydric acid or an alkaline sulphydrate. On these reactions is founded a division of the metals into groups, which forms the basis of the mode of separating them usually adopted in analysis. (See ANALYSIS, INORGANIC, i. 217.)

Sulphydric acid is recognised by the black discoloration it produces on paper moistened with solutions of lead or bismuth, and by the black tarnish it gives to silver-foil.

Persulphide of Hydrogen. H^2S^2?—This compound seems to be the sulphur-representative of peroxide of hydrogen, which it much resembles in its properties. It is made by gradually adding the solution of a persulphide of alkaline earth- or alkali-metal to an excess of hydrochloric acid diluted with twice its bulk of water:

$$CaS^5 + 2HCl = CaCl^2 + H^2S^2 + S^3.$$

The persulphide of hydrogen is formed without any evolution of gas, and separates as a yellowish oily fluid, heavier than water. It has the property of dissolving sulphur to a considerable extent, owing to which circumstance its composition has not been satisfactorily established. Persulphide of hydrogen has a peculiar, sulphurous, disagreeable odour. It produces superficial white eschars on the skin and mouth. It is insoluble in water, but soluble in ether, forming a solution which soon decomposes and deposits crystals of sulphur. It is readily inflammable, and burns with a blue flame. It is possessed of bleaching properties analogous to those of peroxide of hydrogen.

Persulphide of hydrogen is a very unstable substance, and, especially at increased temperatures, undergoes spontaneous decomposition into sulphydric acid and sulphur. By effecting this decomposition in a sealed tube, liquid sulphydric acid may be obtained (p. 203). The stability of the persulphide is increased by the presence of moderately strong acids. Alkalis, on the other hand, promote its decomposition. Hence if, in its preparation, the hydrochloric acid be added to the alkaline persulphide, instead of the persulphide to the acid, no persulphide of hydrogen, but only sulphydric acid and sulphur will be obtained. Under the influence of catalytic agents, such as finely-divided platinum, gold, iridium, and charcoal, which effect the similar decomposition of peroxide of hydrogen into oxygen and water, persulphide of hydrogen undergoes an instantaneous decomposition into sulphur and sulphydric acid. It reduces peroxide of manganese and the oxides of silver and gold, the last two with great violence, and frequently even with ignition. (*Odling's Manual of Chemistry.*)

HYDROGEN, TELLURIDE OF. H^2Te. *Tellurhydric* or *Hydrotelluric acid. Telluretted hydrogen.*—This compound is evolved as a gas, when certain metallic tellurides, the telluride of zinc being generally used, are treated with hydrochloric acid:

$$ZnTe + 2HCl = H^2Te + ZnCl^2.$$

It closely resembles its analogues, sulphydric and selenhydric acids, smells very much like the former, burns with a blue flame, has a slight acid reaction, and dissolves in

Digitized by Google

water, forming a colourless liquid which deposits tellurium when exposed to the air. It precipitates most metals from their solutions in the form of tellurides (*q. v.*)

HYDROHALITE. A native hydrated chloride of sodium, $NaCl.2H^2O$. (Dana, ii. 506.)

HYDROKINONE. See HYDROQUINONE.

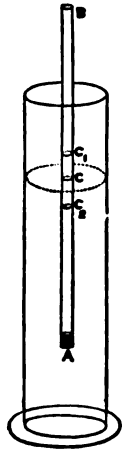
HYDROLEIC ACID. See OLEIC ACID.

HYDROLITE. Syn. with GMELINITE (ii. 924).

HYDROMAGNESITE. *Hydrated carbonate of magnesium*, $4MgO.3CO^2.4H^2O = 3(MgCO^3.H^2O).MgH^2O^2$ or $3(MgH^2CO^4).MgH^2O^2$.—It occurs native in small monoclinic crystals, usually acicular or bladed and tufted, also amorphous or as a chalky crust. Specific gravity = 2·145. Hardness of crystals = 3·5. Lustre vitreous to silky or sub-pearly; also earthy. Colour and streak white. It is found in serpentine at Hrubschitz in Moravia; near Kumi in Negroponte; at Hoboken, New Jersey, and other localities in North America (Dana, ii. 457). A specimen from Texas, Lancaster county, Pennsylvania, analysed by Smith and Brush (Sill. Am. J. [2] xv. 207), gave 36·00 per cent. CO^2, 43·96 MgO, 19·68 water, and 0·36 silica. Artificially prepared hydrocarbonate of magnesium has sometimes the same composition.

HYDROMAGNOCALCITE. Syn. with HYDRODOLOMITE.

HYDROMARGARIC and **HYDROMARGARITIC ACIDS.** Acids of doubtful constitution, which Frémy obtained by treating olive-oil with strong sulphuric acid. (See MARGARIC ACID and PALMITIC ACID.)



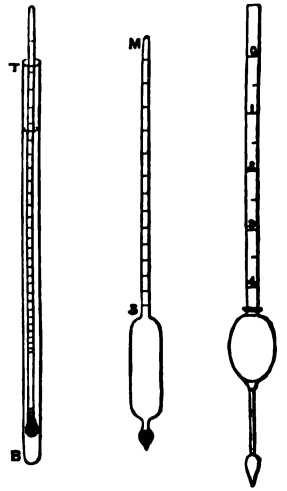
HYDROMELLONE. See MELLONE.

HYDROMETER (ὕδωρ, water; μέτρον, measure). *Gravimeter, Pèse-liqueur;* on the Continent, most commonly called the *Areometer* (ἀραιός, rare, subtle). An instrument which, on being placed in a liquid, shows its specific gravity, either by direct inspection, or by simple adjustment and calculation.

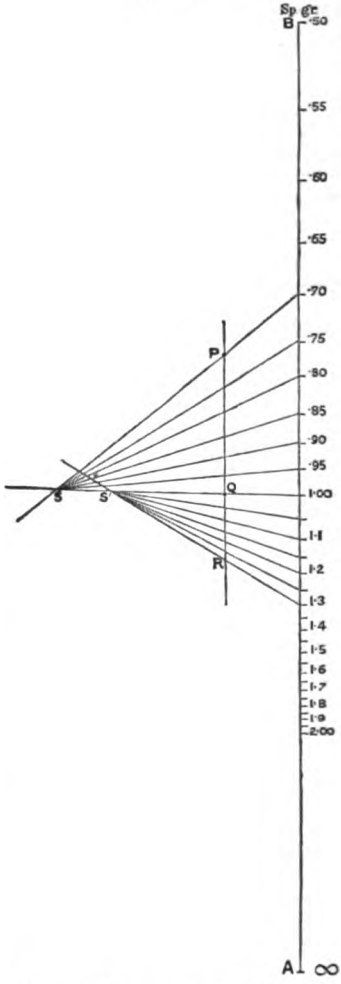
Its action depends on the simple principle of hydrostatics, that a floating body must displace its own weight of liquid. The truth of this principle is seen if we consider that any part of a mass of liquid at rest must be supported by the pressure of the surrounding liquid, and will certainly continue to be supported, so long as it has the same weight and volume: hence it may be conceived to become solid without altering the conditions of equilibrium. Now weight is mere downward pressure, and the solid immersed in a liquid need not weigh so much as an equal volume of liquid, provided that the difference is exactly made up by downward pressure, or weight communicated from another part of the solid, above the surface of the liquid.

Thus, in *fig.* 557, suppose the solid AB to have the same weight as a volume of water equal to the volume of the part AC. When placed in water, the solid will sink up to the point C: for the upward pressure of the water, which usually supports a volume of water equal to AC, will then be exactly sufficient to support the weight of the solid AB. If we now place AB in a liquid of less specific gravity, the weight of AB will be greater than the weight of the volume AC of the liquid, and equal, for instance, to the weight of the volume AC_1. Then by similar reasoning, AB will sink into this lighter liquid up to the point C_1. Again, if AB sink in a third liquid only up to the point C_2, it is obvious as before, that the volume of liquid AC_2 is equal in weight to the solid AB.

Fig. 557.



Now the specific gravities of bodies are, by definition, in the proportion of the weights of equal volumes of the bodies, or, which is the same, in the inverse proportion of the volumes of equal weights. In other words, the specific gravity is less, as it requires a larger volume to make a given weight. Now the volumes AC, AC_1, AC_2, of the respective liquids are all of one weight, that of the solid AB: hence the specific gravities have the inverse proportion of AC, AC_1, AC_2, or if we assume the first (water) to have the specific gravity 1·00, the specific gravities of the others are $\frac{AC}{AC_1}, \frac{AC}{AC_2}$.



The hydrometers commonly used do not differ from the solid body AB above described, except that the part which meets and cuts the surface of the liquid is usually of very narrow section, in order that slight differences in the density of the liquid may cause the hydrometer to rise or sink through a considerable space. The form of those parts of the hydrometer below the liquid has no effect upon the accuracy of the result, but for convenience the lower parts are usually much expanded, in order that they may be proportionally shorter. Several different forms of the hydrometer are shown in *figs.* 558, 559, 560. The hydrometer in *fig.* 558 would indicate specific gravities differing through a considerable range, but without much accuracy. It is accompanied by a tube TB, which holds the liquid under examination. That in *fig.* 559, on the contrary, has

Digitized by Google

a very slender stem (SM), and would indicate with great accuracy any specific gravit within a certain narrow range. Hydrometers are usually made of light glass tu and bulbs blown in a single piece. The chief part of the weight is given by small sh or mercury, carefully adjusted so that the instrument shall sink to a conveni depth in the required liquids, and then sealed up in a small bulb at the lowerm extremity. In other cases, the hydrometer is made of thin gilt brass or silver, as *fig.* 560, but the weight is still placed below, in order that the instrument may fl upright and stiffly.

Fig. 558. *Fig.* 559. *Fig.* 560. *Fig.* 561.

Graduation.—We have yet to consider the nature of the graduation on the stem of any hydrometer which is to give by inspection the specific gravity of the liquid in which it floats. Reverting to *fig.* 557, let the distance AC to which the hydrometer sinks be successively x_0, x_1, x_2, &c. when AB stands in liquids of the densities ρ_0, ρ_1, ρ_2, &c.

Then $\frac{x_1}{x_0} = \frac{\rho_0}{\rho_1}$, $\frac{x_2}{x_0} = \frac{\rho_0}{\rho_2}$, &c. Of these quantities let ρ_0 be the density of distilled water at the temperature 62° F., which we assume as 1·00; call the corresponding length x_0, the unit of length. Then $x_1 = \frac{1}{\rho_1}$, $x_2 = \frac{1}{\rho_2}$ &c., and $x_1 - x_2 = \frac{1}{\rho_1} - \frac{1}{\rho_2}$. Thus we see that equal differences of specific gravity are indicated, not by any equal intervals on the scale, but by the differences of the reciprocals of those specific gravities, or by quantities proportional to them. The scale which must then be employed is to be obtained by calculation, and its character is shown with some accuracy in the divi line AB *fig.* 561.

Until recently, indeed, it was customary to graduate the stem of every hydrome into some series of equal divisions arbitrarily chosen, and the indications were eit used conventionally, without reference to specific gravity at all, or the correspondi specific gravity was ascertained by calculation or reference to a table. It is obviou desirable, however, to adopt the true scale of specific gravities, since this can always constructed with facility and sufficient accuracy.

A mode of graduating hydrometers with accuracy, as practised by Mr. Ackland, described in the Reports of the Jurors of the Exhibition of 1851 (p. 25). It consi of the following processes:

Digitized by Google

1. Ascertaining the exact position of three or more points of the scale, according as the stem of the hydrometer is more or less truly cylindrical.

2. Dividing with great accuracy a scale on boxwood, to show the specific gravities required to be indicated by the hydrometer.

3. Making a reduced copy of the boxwood scale, so as to form a scale, the points of which shall correspond with the ascertained points on the hydrometer-tube. The scale so formed on paper is ready to be engraved on the hydrometer.

For example, suppose it be required for a hydrometer to show specific gravities from 1·00 to 0·700. A bulb is chosen with a stem as uniform as possible, and three points—for instance, ·700, ·850, and 1·000—are ascertained as follows: Load the hydrometer till it sinks in distilled water of the temperature 62° to some marked point convenient for the degree 1·00; let the weight of the instrument then be x. To ascertain the point of the degree ·85, alter the weight of the hydrometer until it is $\frac{1{\cdot}00 \times x}{{\cdot}85}$, and placing it in water, mark where it is cut by the surface. Lastly, alter the weight to $\frac{1{\cdot}00 \times x}{{\cdot}70}$, and mark the point as before, which will correspond with the specific gravity ·700. The original weight x of the hydrometer may then be restored and the tube sealed. This method, requiring the use of no liquid but water, is very convenient, and was suggested to Mr. Ackland by Dr. Clarke of Aberdeen.

The remainder of Mr. Ackland's processes are performed by calculating the reciprocals of the specific gravities required, forming them into a scale, and then reducing this scale and transferring it to the glass tube by a dividing engine of peculiar and ingenious construction.

We have formed the following table of the reciprocals, and their differences. Intermediate degrees can easily be interpolated when necessary.

Specific gravity.	Reciprocal.	Difference of Reciprocals.	Specific gravity.	Reciprocal.	Difference of Reciprocals.
2·00	·500		1·25	·800

			·50	2·000	

We shall now describe a graphical method which the chemist can easily use as a substitute for Mr. Ackland's dividing engine, so as to graduate his own hydrometers with accuracy. Draw a line AB (*fig.* 561) on a sheet of good paper, and lay off upon it, with exactness, as many of the reciprocal numbers or differences, given in the table, as are likely to be required within the range of the hydrometers to be graduated: this may easily be done with the aid of a decimal or diagonal scale and a pair of compasses. The absolute size of this scale is of no importance, except that the larger it is the more accurate will the result probably be.

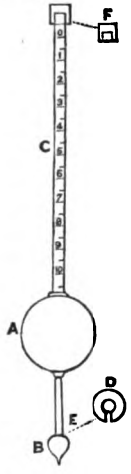
Now suppose the points on a hydrometer have been determined for the specific gravities ·700, 1·00 and 1·30. Draw a line exactly parallel to AB, and measure off distances PQ, QR, equal to the absolute distances of the points on the hydrometric stem, placing the points P, Q, R, as nearly as possible opposite the specific gravities ·700, 1·00, 1·30, on the scale AB. Draw lines through P and the degree ·70, and through Q and the degree 1·00. If these lines never meet, the scale on PQ will be identical with that on AB. But suppose they meet in S: draw lines through S and the several degrees on AB between ·70 and 1·00. Then the intersections of these lines and PQ give the required points for the scale PQ. Next draw a line through R and the degree 1·3. If this also pass through the point S it will indicate that the stem of the hydrometer is perfectly uniform. But wherever S', the point of intersection of Q—1·00 and R—1·30 may be, draw lines from S', through the degrees of AB, giving by their intersection with QR the required points of graduation.

If necessary, other points besides P, Q, R, might, for the sake of accuracy, be

Digitized by Google

determined on the stem of the hydrometer, and the graduation could still be perfo with but little extra trouble, from many successive points of intersection.

The hydrometer scale, when once obtained on paper, can be transferred to the stem of the instrument by the usual process of etching with hydrofluoric acid. glass must be covered with bees'-wax, and firmly fixed, at a proper distance, i same straight line with the divided scale, the degrees of which may then be easi accurately transferred by a beam-compass. For fuller directions on the meth graduating glass tubes, the reader must consult Bunsen's Gasometry (p. 25), als article ANALYSIS OF GASES in this Dictionary (i. 269). Were it desired oft graduate hydrometers, it would be best to engrave the scale AB (*fig.* 561) u glass plate, together with converging lines drawn through the degrees, and then it as Bunsen describes.



The smaller intervals of a hydrometer scale may always be subdivided into parts by estimation, or otherwise, without appreciable error.

The delicacy of the hydrometer may always be increased to an indefinite exte lessening the diameter of the stem; but in the same proportion it becomes more li in range, and troublesome to use. The adhesion of air-bubbles is a great sou discrepancy, especially in the metal instruments, and for this reason all hydrom should be made with as smooth and small a surface as possible.

Again, the attraction of the glass or metal stem for the water causes the surf water to rise up against the stem in a parabolic curve. This phenomenon alo preventing us from getting an exact reading, is almost enough to condemn the h meter as a standard instrument of measurement. Fortunately the hydrostatic ba and the specific gravity bottle are means of determining specific gravities unlimited accuracy and considerable ease. The hydrometer takes a subordinate and is chiefly employed in approximately determining the strength of solutio mixtures of liquids. It often effects a wonderful saving of time or trouble, an person frequently occupied with liquids of a variable strength or composition s have hydrometers suitably constructed in range and delicacy for testing them. treat the instrument as suitable for exact scientific measurement, and to investigat determine corrections for every little error which might arise, would be a mis We accordingly proceed to describe various well-known forms of the hydrometer, v are extensively used for practical purposes.

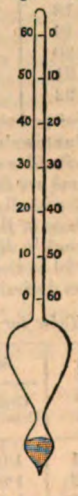
Sykes' *Hydrometer* is of importance because, by Act of Parliament (58 Geo c. 28; see also 3 & 4 Will. IV. c. 52 § 123) it is employed in the collection of th cise revenue of the United Kingdom levied upon spirituous liq of which of course the strength must be determined. It is ma brass (*fig.* 562) with a spherical bulb A, 1½ inch in diameter, a w (B) to sink it and maintain it upright in the liquor, and a flat form stem C, 8½ inches long, divided into ten parts, each of whi again divided into two parts. A series of nine weights of the fo accompany the instrument, having the proportions 10, 20, 30, 90. These weights are placed in succession at E, until the in ment is found to sink in the liquor up to some point of the di scale. The numerical reading of the scale at the point where cut by the surface of the liquor, added to the number on the w employed, gives the required result. But the temperature of liquor must also be observed, and the proportion of spirit it con ascertained by a table in which the variables are the degrees o hydrometer and thermometer.

Fig. 562.

The supernumerary weight F may be placed on the summit o stem, and then causes the hydrometer, loaded with the cir weight 60, to sink to the same point in pure water to which it w otherwise sink in proof spirits. Concerning the determinati the proportion of alcohol contained in a mixture with water ALCOHOLOMETRY (i. 81).

Jones' *Hydrometer* is an improvement on that of Sykes. It i companied by three detached weights, so that, according as thes used or not, the hydrometer may have four different degrees of we Corresponding to these are four separate scales on the sides o stem, which is made square for the purpose. A thermometer, also with four diff scales, is included in the lower part of the instrument, and the whole is so cont that the number of gallons in the 100 under or over *proof* may be read off.

The following formulæ apply to any hydrometer, as for instance Sykes' or Jone which weights are added below the liquid.



Let w = weight of hydrometer.
v = volume of hydrometer up to the bottom of the scale.
m = area of section of stem (supposed uniform).

Cartier's *Hydrometer* is sometimes used on the Continent. The degree of its scale 22 coincides with the degree 22 of Baumé, but above and below this point, the degrees of Baumé are diminished in the ratio of 16 to 15. This hydrometer is only constructed for liquids lighter than water, and any who may require it can easily reduce its readings to those of Baumé, and make use of the table already given for Baumé's hydrometer.

Beck's *Hydrometer* has a scale of which 0 corresponds to the specific gravity 1·00, and 30 to that of ·850, and the scale is extended in equal parts above or below 0, as far as desirable. The following tables are necessary:

Table for converting degrees of Beck's *Hydrometer into real Specific Gravities.*

Twaddell's *Hydrometer* is often used in England for testing liquids denser than water. It is graduated in such a manner that the reading, or number of degrees, multiplied by 5 and added to 1000, gives the specific gravity with reference to water as 1000. Thus,

10° Twaddell indicates the specific gravity 1050 or 1·050,
90° " " 1450 or 1·450.

Then the weight of the substance is obviously $w_1 - w_3$. Now transfer the subst to one of the lower pans, that which is concave downwards being used when substance is lighter than water, and has to be forced under. The instrument again be adjusted so as to float in water at the usual level, and it will be found some further weight has to be added for this purpose. Let the weight now in pans be w_4. Then the specific gravity of the substance is $\frac{w_1 - w_3}{w_4 - w_3}$.

This instrument becomes more and more delicate and accurate in its indication the stem is of smaller diameter. As actually constructed by the inventor, the s was a piece of hardened steel wire $\frac{1}{20}$ inch in diameter. But the more delicate, more troublesome does the instrument become in use; the adherence of water to parts above the surface, the adherence of air to those below, and the inevitable cha of temperature in the water, are sources of unavoidable error. The chemist, in balance and specific gravity bottle, has always at hand the means of ascertai specific gravities with any degree of accuracy, and is not likely to use Nichols hydrometer. But this instrument is a valuable companion to the scientific trave since, besides its use in taking specific gravities, it may be employed in place balance for ascertaining any small weight.

Having now given all that it is likely to be practically useful concerning hydrometer, we think it quite needless to describe all the minute varieties of const tion and arbitrary scales proposed by Homberg, Clarke, Gay-Lussac, Dica, Riel Adie, Quin, Guyton, Speers, Charles, and others. Much information is given in *Handwörterbuch der Chemie*, 2te Aufl., &c., ii. 165–190.

The hydrometer is said to have been first invented by Hypatia, daughter of T Alexandrinus, who flourished about the end of the fourth century, but the disco is sometimes ascribed to Archimedes. However this may be, the English philoso Robert Boyle appears to have first brought it into use, having described it in Trans. for 1675 (x. 329), or *Boyle's works* (1772, iv. 204). His instrument was al identical with Nicholson's hydrometer, and was especially intended to determine fineness of gold alloys, being hence called a "*New Essay Instrument*."

Many references concerning the history and varieties of the hydrometer wil found in *Young's Lectures* [1845] i. 240.—*Bénoit's Théorie Générale des Pèse-liqu* [1821], is a work we have not been able to meet with. Clarke's hydrometer (Trans. xxxvi. [1730], p. 277), Brewster's Capillary Hydrometer, Staktometer, or I measurer, are described in the Edinburgh Cyclopædia, xi. pt. ii. p. 442.—W. S. J.

HYDRONICKELMAGNESITE, also called *Pennite*. A variety of hydro mite (p. 191) containing 2 per cent. or less of carbonate of nickel, with water. It f pale-green or whitish incrustations, having a surface of minute spherules, and o together with emerald-nickel, into which it graduates, also with chromic iron, at T Lancaster county, Pennsylvania, and according to Heddle, at Swinaness, in U Shetland. Hermann found in it 44·54 CO^2, 20·10 CaO, 27·02 MgO, 1·25 Na^2O, FeO, 0·40 MnO, 0·15 Al^2O^3, and 5·84 H^2O = 100. (Dana, ii. 457.)

HYDROPHANE. A variety of opal, which becomes transparent when imm in water.

HYDROPHILITE. A name applied to chloride of calcium.

HYDROPHITE, also called *Jenkinsite*. A hydrated silicate of magnesium iron, which occurs massive, and sometimes fibrous. Specific gravity 2·46— Hardness = 3·5. Lustre, feeble, subvitreous. Colour, mountain-green to blac green: streak pale; translucent to opaque.

	SiO^2	FeO	MnO	MgO	Al^2O^3	V^2O^3	H^2O

HYDROQUINONE. *Hydrochinone, Hydrokinone* (Wöhler, Ann. Ch. Pharm. xlv. 354; li. 150; Hesse, *ibid.* cx. 194; cxiv. 292).—This name is applied to two substances, one colourless and the other green.

COLOURLESS HYDROQUINONE (*Pyroquinole*), $C^6H^6O^2$, isomeric with oxyphenic acid, is the chief product of the dry distillation of quinic, carbohydroquinonic, and oxysalicylic acids (*q. v.*), and is likewise produced by the action of reducing agents (stannous chloride or sulphurous acid) on quinone, from which it differs by 2 at. H; also, together with a brown crystalline body containing $C^{18}H^{14}N^2O^2$, by the action of phenylamine on quinone (A. W. Hofmann, Proc. Roy. Soc. xiii. 4):

$$\underset{\text{Phenylamine.}}{2C^6H^7N} + \underset{\text{Quinone.}}{3C^6H^4O^2} = \underset{\text{Brown crystals.}}{C^{18}H^{14}N^2O^2} + \underset{\text{Hydroquinone.}}{2C^6H^6O^2}.$$

Preparation.—1. The distillate, mixed with solid particles, which is obtained by the dry distillation of quinic acid, is filtered from tar, and again, after cooling, to separate benzoic acid; the yellow, heavy, oily mixture of benzene, phenic acid and salicylous acid, is distilled from the filtrate; the brown residue in the retort is evaporated and left to cool till benzoic acid crystallises out; the mother-liquor is diluted with water, which makes the liquid milky and separates tar; and the resulting filtrate is evaporated till the hydroquinone crystallises out.—2. Sulphurous acid gas is passed through warm water saturated with quinone, and having quinone also suspended in it, till all the quinone is dissolved, and the liquid appears colourless; the solution is then gently evaporated to the crystallising point, and the crystals are purified by pressure and recrystallisation.—It is not necessary previously to remove the sulphuric acid by carbonate of barium.—A saturated aqueous solution of quinone may also be mixed with aqueous hydriodic acid, and the watery liquid, after filtration from the iodine, evaporated to the crystallising point.

Properties.—Hydroquinone forms transparent, colourless, rhombic crystals exhibiting the combination, $\infty\breve{P}\infty$. $\infty P\infty$. P. oP (Hesse). It sublimes, when heated, in shining laminæ, like benzoic acid; melts at 177·5° and solidifies to a crystalline mass at 163°. It is inodorous, has a sweetish taste, and is neutral to vegetable colours. It dissolves easily in *water*, especially when hot, also in *alcohol* and in *ether*. From solutions of *alkaline sulphites*, it crystallises unaltered, sometimes however in sulphur-yellow rhombohedrons or long four-sided prisms, resembling the sulphydrates of hydroquinone. (Hesse.)

Decompositions.—1. Hydroquinone, suddenly heated above the boiling point, is partially decomposed into quinone and green hydroquinone. When passed in the state of vapour through a glass tube at a low red heat, it is resolved into quinone and hydrogen (Hesse).—2. *Oxidising agents*, viz. chlorine, chromate of potassium, sesquichloride of iron, or nitrate of silver, convert hydroquinone dissolved in water into green hydroquinone, with formation of hydrochloric acid, chromic oxide, or protochloride of iron and hydrochloric acid, or with precipitation of silver.—3. Strong *nitric acid* converts it almost wholly into oxalic acid (Hesse).—With *hydrochloric acid and chlorate of potassium* it yields tetrachlorquinone (chloranil) (Hesse).—4. The aqueous solution of hydroquinone imparts a saffron-yellow colour to *cupric acetate*, and when heated throws down cuprous oxide, quinone volatilising at the same time.—5. *Ammonia* imparts to it a brown-red colour, and yields on evaporation a brown mass like ulmic acid. *Potash* acts in like manner. (Wöhler.)

Hydroquinone dissolves in a moderately concentrated hot solution of neutral *acetate of lead*, and the solution, on cooling, yields prisms containing $C^6H^6O^2.C^4H^6PbO^4 + \frac{2}{3}H^2O$. These crystals give off 5·23 per cent. of water (nearly $\frac{2}{3}$ at.) over sulphuric acid.

Sulphydrates of Hydroquinone.—There are two of these salts. The first, containing $4C^6H^6O^2.H^2S$, is obtained in colourless prisms by passing sulphydric acid gas into a saturated solution of hydroquinone heated to 40°.—The second $3C^6H^6O^2.H^2S$, is obtained, by passing sulphydric acid into a cold saturated solution of hydroquinone, in small shining crystals, which redissolve when heated if the passage of the gas be continued, the solution, as it cools, yielding the compound in very regular colourless rhombohedrons. These crystals remain unaltered when dry, but water eliminates sulphydric acid from them, and on boiling the solution, hydroquinone is reproduced.

GREEN HYDROQUINONE OR QUINHYDRONE. $C^{12}H^8O^4 = C^6H^6O^2.C^6H^4O^2$.—This compound may be regarded either as a compound of quinone and colourless hydroquinone, or as a double molecule of the latter compound *minus* 2 at. H, or again as a double molecule of quinone ($C^{12}H^8O^4$) *plus* 2 at. H.

It is produced:—1. By mixing the aqueous solutions of quinone and hydroquinone, whereupon it is immediately precipitated in the crystalline form.—2. By combining aqueous quinone with a quantity of hydrogen not sufficient for the formation of colourless hydroquinone; *e. g.* aqueous quinone mixed with sulphuric acid at the

Digitized by Google

negative pole of the galvanic circuit; quinone mixed with sulphuric acid in co with zinc; aqueous solution of quinone with gradual addition of dichloride of ti protosulphate of iron, or sulphurous acid, or alloxantin, the latter being converted alloxan.—3. By the partial dehydrogenation of aqueous hydroquinone; *e.g.* spongy platinum or animal charcoal moistened with the solution is exposed to the when chlorine gas is passed through aqueous hydroquinone, or that liquid is mixed nitric acid, chromate of potassium, sesquichloride of iron, or nitrate of silver.— mixtures prepared according to (2) or (3) with concentrated solutions, assume while a black-red colour, and then become filled with long, green, metallic-looking pr of quinhydrone; but if the solutions are too dilute, the quinhydrone remains disso and is decomposed, emitting the odour of quinone.—The largest crystals are obta by at once adding to a saturated aqueous solution of quinone (or even to its mother-liq a quantity of aqueous sulphurous acid just half sufficient for the formation of hy quinone.

Properties.—Quinhydrone forms very long and thin green prisms, having a met lustre, like the wings of gold-beetles or humming birds, and brighter even murexid; they appear red-brown by transmitted light when strongly magnified. melts easily to a brown liquid, and sublimes partly undecomposed in green lam Smells slightly like quinone, and has a pungent taste.

It dissolves sparingly in cold *water*, abundantly and with red-brown colour in water, separating as it cools. *Alcohol* and *ether* dissolve it readily, forming yello red solutions. *Ammonia* dissolves it with green colour. The aqueous solution f with *acetate of lead* a bright greenish-yellow precipitate, quickly changing to grey.

Decompositions.—1. When quinhydrone is heated, it sublimes partly undecomp partly converted into yellow quinone.—2. When it is boiled with water, quinone di over, and the remaining dark red-brown liquid contains, together with a large qua of hydroquinone, a brown tar, which separates partly on cooling, partly on subseq addition of water.—3. The green solution of quinhydrone in *ammonia* quickly ass a dark red-brown colour on exposure to the air, and leaves a brown amorphous when evaporated.—4. Quinhydrone is converted into colourless hydroquinon aqueous *sulphurous acid*, *stannous chloride*, or *zinc and sulphuric acid*, but no hydriodic acid or tellurhydric acid.—5. The aqueous solution quickly reduces *ni of silver*, on addition of ammonia.

Derivatives of Hydroquinone.

Carbohydroquinonic acid. $C^7H^6O^4 = C^6H^6O^2.CO^2 = \left.\begin{matrix}(C^7H^5O)'''\\ H^3\end{matrix}\right\}O^3$. (O. He Ann. Ch. Pharm. cxii. 527, cxiv. 292; cxxii. 22; E. Lautemann, *ibid.* cxx. 31 An acid produced:—1. By the action of bromine on aqueous quinic acid.—2. By ing quinic acid to above 200°.—3. Small quantities of it are likewise obtained by action of chlorate of potassium and hydrochloric acid on dilute aqueous quinic or of peroxide of manganese and sulphuric acid on aqueous quinate of calcium. (Hes

Preparation.—Bromine is added to aqueous quinic acid by portions of 10 drops till a portion of it remains undissolved, even after the liquid has been freque agitated and left to stand for 12 hours. The solution is then decanted from the dissolved bromine, diluted, filtered, and mixed with carbonate of lead, as long brisk evolution of gas is thereby set up, and bromide of lead produced. The filt evaporated to a thick syrup on the water-bath, and shaken up with about 5 vol. et yields to this liquid carbohydroquinonic acid, which after the ether has been dist off, remains as a brown crystalline residue. It is purified by re-crystallisation water containing hydrochloric acid, with help of animal charcoal.—Or the solu treated with bromine and filtered, is mixed with carbonate of lead, till this salt be to take up organic substances; the filtrate is precipitated with solution of neu acetate of lead, and then, after this precipitate has been collected, a further precipi is obtained by addition of ammonia. By decomposing the precipitates suspende water with sulphydric acid, then boiling up and diluting the filtrate, carbohy quinonic acid is obtained from the first precipitate. The acid obtained from the sec lead-precipitate still retains unaltered quinic acid, from which it may be separ by ether. (Hesse.)

Properties.—Carbohydroquinonic acid crystallises from its aqueous solution 1 at. water ($C^7H^6O^4.H^2O$), in furcate groups of needles, also in rhombic lamina granular crystals. It is dimorphous. The granular crystals are distorted tw belonging to the monoclinic system. The needles are rhombic prisms, having acute edges perpendicularly truncated, cleavable at right angles to the prismatic f (Hesse).—The crystallised acid dissolves in 40 or 50 pts. of *water* at 17°, very ea

Digitized by Google

in boiling water and in *alcohol*, but is insoluble in *ether*. It has a sour and bitter taste and reddens litmus. Heated to 100° it gives off, on the average, 10·5 per cent. water, leaving the anhydrous acid, $C^7H^6O^4$, which melts at 207° (corrected) with partial decomposition, and solidifies in the radio-crystalline form between 160° and 170° (Hesse). When cautiously heated, it sublimes with partial decomposition. (Lautemann.)

Decompositions.—1. Carbohydroquinonic acid is resolved by fusion, and with great facility when heated to 240°, into carbonic anhydride and hydroquinone, $C^7H^6O^4 = C^6H^6O^2 + CO^2$ (Hesse). When it is heated with pumice, pyrocatechin is obtained instead of hydroquinone, the former being apparently capable of passing, under circumstances not exactly known, into hydroquinone (Lautemann).—2. It is not altered by boiling dilute *nitric acid*; the concentrated acid converts it, with rise of temperature and evolution of nitrous acid, into oxalic acid, together with a trace of a yellow substance.—3. *Sulphuric anhydride* dissolves it, without evolution of gas, forming a blue liquid, brownish by reflected light. No conjugated sulphuric acid can be obtained from this solution.—In *oil of vitriol*, carbohydroquinonic acid dissolves slowly, and chars when heated.—4. *Bromine* dissolves slowly in the aqueous acid, with evolution of gas.—5. Aqueous carbohydroquinonic acid, in contact with *acid carbonate of calcium* and air, acquires a dark, nearly black colour, and deposits a black precipitate, which effervesces with acids (Hesse).—6. From *cupric hydrate* and *potassio-cupric tartrate* aqueous carbohydroquinonic acid separates cuprous oxide; from *mercuric* and *silver-salts* it separates the metal. Dilute aqueous carbohydroquinonic acid, mixed at 8° or 10° with neutral solution of *nitrate of silver*, becomes dark-coloured in a quarter of an hour, even in the dark, and in three hours separates metallic silver (Hesse). According to Lautemann it reduces nitrate of silver when heated, but not in the cold.

The carbohydroquinonates are, for the most part, easily soluble in water, sparingly soluble or insoluble in alcohol. Hesse regards the acid as monobasic, and the ammonium-salt as a basic salt, in which 1 at. ammonia takes the place of water of crystallisation, $C^7H^5(NH^4)O^4.NH^3$. The formula $\left.\begin{matrix}(C^7H^5O)'''\\H^3\end{matrix}\right\}O^3$ represents it as triatomic but monobasic, like glyceric acid (ii. 875). Strecker (*Handwörterb.* ii. [2], 996), regards the acid as dibasic. Carbohydroquinonic acid decomposes the carbonates of the alkaline earths. Its salts turn brown in the air. In contact with a small quantity of sesquichloride of iron, they acquire a violet colour; with a larger quantity, a fine purple-violet to chrome-green colour especially in neutral solution. (Hesse.)

Ammonium-salts.—When dry ammonia-gas is passed over dry carbohydroquinonic acid, 100 pts. of the acid take up from 22·3 to 22·7 pts. of ammonia (2 at. = 22·08 NH^3), without giving off water. The resulting compound, freed from excess of ammonia by standing over oil of vitriol, contains 44·7 per cent. C, and 6·2 H, corresponding to the formula, $C^7H^5(NH^4)O^4.NH^3$ (calc. 44·68 per cent. C, and 6·38 H). When exposed to moist air, it quickly gives off ammonia, and dissolves, with alkaline reaction, in water and alcohol. The latter solution, when evaporated, deposits small acid crystals. Hydrated ether partially dissolves the ammonium-salt, leaving a portion, perhaps consisting of $C^7H^5(NH^4)O^4.H^2O$. An ether-alcoholic solution of carbohydroquinonic acid becomes turbid when ammonia gas is passed over it, and then clear, depositing concentric groups of prisms. Brown substances are formed at the same time. (Hesse.)

Lead-salt.—From aqueous carbohydroquinonic acid, an aqueous or alcoholic solution of neutral acetate of lead throws down an amorphous yellow precipitate, easily soluble in nitric acid, with difficulty in acetic acid. Part of the carbohydroquinonic acid dissolves at the same time in the acetic acid which is set free, so that the filtrate still gives a precipitate with ammonia. (Hesse.)

The *potassium-salt* is precipitated from its aqueous solution by alcohol in the form of a syrup.—The *manganous salt* forms small prisms, easily soluble in water.—The *zinc-salt* forms laminæ.—Aqueous carbohydroquinonic acid yields a greyish-yellow precipitate with *tartar emetic*; and with *ferric hydrochlorate*, a dark green solution changing to violet on addition of acid carbonate of sodium, or of tartaric acid, ferric hydrochlorate, and ammonia. It does not precipitate *gelatin*.

The following acids give reactions very similar to those of carbohydroquinonic acid: 1. *Morintannic acid* and *Morin*, which, according to Hlasiwetz, are isomeric with carbohydroquinonic acid.—2. *Deuterocatechuic acid*, $C^6H^6O^4$, and *Tricatechuic acid*, $C^7H^{10}O^4$. These two acids are supposed by Strecker (Ann. Ch. Pharm. cxviii. 280) to exist in catechu, inasmuch as he regarded the pyrocatechin, first as the one, then as the other of these acids, and finally, as a mixture of the two.—3. *Protocatechuic acid.* This acid, according to Lautemann (Ann. Ch. Pharm. cxx. 315), must be regarded as identical with carbohydroquinonic acid, since the latter acid, when

Digitized by Google

heated with pumice, is capable of yielding pyrocatechin. But according to Hesse (Ann. Ch. Pharm. cxxii. 221), the two acids react differently with cupric tartrate, and must therefore be regarded as only isomeric.—4. *Oxysalicylic acid.* With regard to this acid, Lautemann thinks it probable that it may be capable of passing into carbohydroquinonic acid (or the latter into oxysalicylic acid).—5. *Hypogallic acid.*

Ethyl-carbohydroquinonic acid, $C^9H^{10}O^4 = \left.\begin{matrix}(C^7H^3O)'''\\H^2.C^2H^5\end{matrix}\right\}O^3$. *Carbohydroquinonic ether.*—To prepare this compound, carbohydroquinonic acid is dissolved in alcohol of 90 per cent.; the solution is saturated with hydrochloric acid gas; the alcohol is distilled off in the water-bath; the residue is shaken up with ether, as long as that liquid takes up a substance which colours ferric chloride; the ether is then distilled off; the brown crystalline residue is shaken up with boiling, very dilute alcohol, and a small quantity of carbonate of sodium; the solution is left to cool; and the acid is again exhausted with ether. The ethereal solution when evaporated leaves coloured crystals, which may be decolorised by again treating them with dilute alcohol, soda, and ether. It forms colourless prisms united in radiate groups, neutral, melting at 134° (corrected), and becoming crystalline again at 124·3°.

The ether melts in boiling water before dissolving; dissolves easily in *alcohol*, and especially in common *ether*. The aqueous solution, added to *neutral acetate of lead*, forms a white amorphous precipitate soluble in acetic acid; it colours *ferric hydrochlorate* violet, changing to purple-violet on addition of a larger quantity of the iron-salt, and finally to chrome-green. It reduces *mercuric chloride, nitrate of silver*, and *potassio-cupric tartrate.* (Hesse, *loc. cit.*)

Chlorinated Hydroquinones. (Wöhler, Ann. Ch. Pharm. li. 155.—Städeler, *ibid.* lxix. 132, 306, 321.)—These compounds are produced by the action of reducing agents on the corresponding chlorinated derivatives of quinone: they are most easily prepared by means of sulphurous acid. They bear a greater resemblance to hydroquinone in proportion as they contain less chlorine. They act like weak acids, their alcoholic solutions yielding white precipitates with acetate of lead, the quantity of the precipitate being increased by addition of ammonia. The chlorine in these compounds does not exhibit its usual reaction with nitrate of silver. By oxidising agents, viz. by nitric acid and sesquichloride of iron, they are converted either into the corresponding chlorinated quinones, or compounds of these with the chlorinated hydroquinones.

Monochlorinated Hydroquinone, $C^6H^5ClO^2$, forms tufts of colourless prisms, very soluble in water, alcohol and ether, and liquefying in contact with the vapour of ether. It melts easily, and sublimes in white laminæ, with partial decomposition. Its aqueous solution reduces nitrate of silver. It dissolves in ammonia, forming a dark-blue solution, changing to green, yellow, and red-brown.

Dichlorinated Hydroquinone, $C^6H^4Cl^2O^2$, forms beautiful nacreous crystals, which melt at 164°, and begin to sublime at 120°. It reddens litmus; dissolves sparingly in cold water, easily in boiling water, also in alcohol, in ether, and in hot acetic acid; sparingly in boiling hydrochloric acid; it is soluble also in hot concentrated sulphuric acid, and separates on cooling. With dilute potash it forms a colourless solution, which on exposure to the air turns green, then red, and deposits a violet powder. With ammonia, it forms a yellow solution, which reddens in contact with the air, and deposits a brownish precipitate.

Trichlorinated Hydroquinone, $C^6H^3Cl^3O^2$, forms colourless laminæ, or flattened prisms melting at a little above 130°, and subliming in iridescent scales. It dissolves readily in alcohol and in ether; the alcoholic solution reddens litmus. It dissolves in potash and in ammonia, forming green solutions, which turn first red, then brown, and yield copious precipitates with hydrochloric acid.

Tetrachlorinated Hydroquinone, $C^6H^2Cl^4O^2$, forms colourless, nacreous laminæ, insoluble in water, very soluble in alcohol and ether; its solutions redden litmus. When heated, it begins to turn brown at 160°, the colour becoming stronger towards 220°; it then sublimes rapidly, but does not melt till more strongly heated; the melted mass crystallises on cooling. It dissolves in potash and in ammonia. The potash solution, saturated hot, deposits on cooling, prismatic crystals, apparently consisting of a potassium-salt.

Octochlorinated Acetyl-dihydroquinone, $C^{14}H^6Cl^8O^5 = C^{12}H^3(C^2H^3O)Cl^8O^4$ (Hesse, Ann. Ch. Pharm. cxiv. 292).—Produced by passing sulphurous anhydride into a mixture of tetrachloroquinone and glacial acetic acid, then evaporating and subliming:

$$2C^6Cl^4O^2 + C^2H^4O^2 + H^2O + 2SO^2 = C^{14}H^6Cl^8O^5 + 2SO^3.$$

It forms colourless laminæ, which melt at 230°, dissolve easily in ether, alcohol, hot benzene, and strong acetic acid, but are nearly insoluble in water.

The *barium-salt*, $C^6H^4Ba''S^2O^8.4H^2O$, forms beautiful monoclinic prisms, with gles of 113° 4′. When heated, it gives off suffocating vapours, hydroquinone, nhydrone, and water, leaving a residue of charcoal. The salt dried in the air, or r oil of vitriol, gives off at 90° from 10·8 to 11·5 per cent. water (3 at. = 11·31 per t. H^2O), then between 120° and 160° an additional 3·3 per cent. (1 at. = 3·77 per t. H^2O), corresponding in all to 4 at. The salt dissolves readily in boiling water, with ficulty in cold water, and in alcohol either cold or boiling, but is insoluble in ether.

The *calcium-salt* resembles the barium-salt.

The *lead-salt*, $C^6H^4Pb''S^2O^8.Pb''H^2O^2$, is separated from the concentrated solution of barium-salt by neutral acetate of lead, as a bulky precipitate, which quickly changes o yellowish microscopic crystals having a silky lustre. When heated, it assumes a non-yellow colour, and becomes carbonised. It is nearly insoluble in water and tic acid, easily soluble in nitric acid, precipitable by ammonia.

The *potassium-salt*, $2C^6H^4K^2S^2O^8.3H^2O$, is obtained by neutralising the aqueous d with carbonate of potassium, and separates with the same composition, even from utions containing 2 at. acid to 1 at. potash. It forms colourless prisms having a ine taste, easily soluble in water, sparingly in alcohol. They retain 6·9 per cent. ter over oil of vitriol, give off the whole at 150°, and decompose when melted.

2. *Sulphodihydroquinonic acid*, $C^{12}H^{16}SO^9 = 2C^6H^6O^2.SO^3.2H^2O$.—Produced the action of fuming sulphuric acid on hydroquinone. The solution, which is formed thout evolution of gas, yields, when saturated with carbonate of barium, a barium- t, which crystallises in concentrically grouped needles containing $C^{24}H^{30}Ba''S^2O^{18}$. is salt is easily soluble in water and in aqueous alcohol, sparingly soluble in abso- e alcohol, and is precipitated therefrom in flocks by ether.

3. *Disulphodihydroquinonic acid*, $C^{12}H^{14}S^2O^{11} = 2C^6H^6O^3.2SO^3.H^2O$.—Hydro- none exposed to the vapour of sulphuric anhydride deliquesces and yields this acid. e *potassium-salt*, $C^{12}H^{12}KS^2O^{11}$, crystallises in colourless monoclinic prisms or in ttened, sharp-pointed needles, easily soluble in water and in hot alcohol. The solu- n treated with ferric hydrochlorate acquires a transient dark-blue colour; it forms a ite precipitate with ammoniacal acetate of lead, and reduces silver from the nitrate.

HYDROSALICYLAMIDE. $C^{21}H^{15}N^2O^3 = N^2(C^7H^6O)^3$. *Salhydramide. Salicylide. Hydride of Azosalicyl* (Ettling, Ann. Ch. Pharm. xxxv. 261).—This compound roduced by the action of ammonia on hydride of salicyl (salicylous acid):

$$3C^7H^6O^2 + 2NH^3 = C^{21}H^{15}N^2O^3 + 3H^2O.$$

e hydride of salicyl is dissolved in 3 or 4 times its volume of cold alcohol, and a ntity of ammonia is added equal to that of the hydride of salicyl employed. The ution then immediately yields yellowish-white needles, and soon solidifies in a mass. applying a gentle heat, the product dissolves completely, and the liquid, on cooling, posits crystals of hydrosalicylamide.

Hydrosalicylamide crystallises in triclinic prisms, without modification. Angle P : $\infty P'$ = 117° 30′; oP : $\infty'P$ = 103° 30′; oP : $\infty P'$ = 93° 30′. It appears to insoluble in *water*, and dissolves but sparingly in cold *alcohol*, but quickly in about pts. of boiling alcohol. At 300° it melts to a yellow and brownish mass, yielding white, very light sublimate. At a higher temperature it carbonises. It is not omposed by weak *potash-ley* in the cold, but on boiling it gives off ammonia and ns salicylide of potassium. Dilute *acids* also do not decompose it in the cold, but heating, ammonia is produced, and hydride of salicyl is set free. With an alcoholic ution of *sulphydric acid*, it yields hydride of sulphosalicyl:

$$\underset{\text{Hydrosalicyl-amide.}}{C^{21}H^{15}N^2O^3} + 3H^2S = \underset{\text{Hydride of sulpho-salicyl.}}{3C^7H^6OS} + 2NH^3.$$

Hydrosalicylamide forms several salts in which part of the hydrogen is replaced by allic radicles.

The *cupro-cuprammonic salt*, $C^{42}H^{30}Cu^2(N^2H^6Cu)''N^4O^6$, is obtained by mixing a very ute and slightly cooled alcoholic solution of hydrosalicylamide with ammoniacal tate of copper (acetate of cuprammonium). The liquid immediately acquires a fine erald-green colour, and gradually deposits brilliant laminæ of the same colour, the ution being at the same time decolorised. The crystals are insoluble in water and alcohol; they dissolve in cold dilute acids, but are reprecipitated on saturating the ution with an alkali. Strong mineral acids decompose them completely, liberating ride of salicyl. Dilute potash does not decompose them without the aid of heat, even then but slowly. They melt when heated, and yield by distillation an oil ch solidifies on cooling, in a crystalline mass having the odour of gum-benzoin.

Ferrico-ferricammonic salt, $C^{21}H^{15}fe^2(NH^3fe)N^2O^3$*.—To prepare this salt, an aqueous

HYDROZINCITE. See ZINC-BLOOM.

HYDURILIC ACID. $C^8H^6N^4O^6$.—An acid belonging to the uric acid gr discovered by Schlieper (Ann. Ch. Pharm. cvi. 11), and further investigated Baeyer (*ibid.* cxxvii. 11). Schlieper, who assigned to it the formula $C^{12}H^9N^3$ once obtained it accidentally in treating uric acid with dilute nitric acid, and conc trating the mother-liquor remaining after the alloxan (i. 135) had crystallised c but he did not succeed in preparing it a second time. It was really produced by decomposition of dialuric acid, which is one of the products of the action of nitric a upon uric acid (ii. 965), and in Schlieper's experiment was decomposed by the hea the sand-bath in which the syrupy liquid had been allowed to remain.

Baeyer obtains hydurilic acid by heating dialuric acid with glycerin (which merely as a solvent) to about 160°, the dialuric acid then splitting up into hyduril of ammonium, formic acid, and carbonic anhydride:

$$\underset{\text{Dialuric acid.}}{5C^8H^6N^2O^4} = \underset{\text{Hydurilate of ammonium.}}{2C^8H^5(NH^4)N^4O^6} + CH^2O^2 + 3CO^2.$$

Preparation from Uric acid.—The uric acid is first converted into alloxan Schlieper's method of oxidation with hydrochloric acid and chlorate of potassi (i. 135); and the alloxan, after being dissolved in lukewarm water, filtered from the altered uric acid, and decolorised if necessary with pure animal charcoal, is conver into dialuric acid by reduction with stannous chloride. For this purpose, a quant of tin equal to the weight of uric acid employed, is dissolved in excess of str hydrochloric acid; the still hot liquid is added all at once to the alloxan solution; more hydrochloric acid is added till the volume of the liquid amounts to 4 litres fo pound of uric acid decomposed. The preceding proportions must be carefully observ for with a smaller proportion of tin, alloxantin is obtained instead of dialuric ac and unless a large excess of hydrochloric acid is used, dialurate of tin separates hard crusts, very difficult to decompose. On leaving the strongly acid solution stand for a day, dialuric acid crystallises out in yellowish stellate groups of short fo sided prisms, which must be quickly washed, and dried in a vacuum. The quan obtained amounts to about 50 per cent. of the uric acid employed.

To convert the dialuric acid into hydurilic acid, 9 pts. of the perfectly dry substa is mixed in a capacious flask with 5 pts. of concentrated glycerin (as it is obtained evaporation in a basin till its temperature rises to 160°), and heated in an oil-bath to 1 —150°. A brisk and regular evolution of carbonic anhydride then takes place, and soon as this ceases and the contents of the flask have become solid, the temperatur raised for a short time to 160°, and the glycerin, after cooling, is removed by washi A yellowish-white granular powder is then left, consisting of acid hydurilate ammonium (p. 221). The glycerin takes no part in the reaction, but acts merely a solvent.

To obtain the free acid, it is best to convert the acid ammonium-salt into a copper-s and decompose this salt with hydrochloric acid. The crude ammonium-salt is dissol in boiling water, ammonia is added in slight excess, and solution of cupric sulphat added to the filtrate. The liquid then assumes a dark-green colour, and, if hot, depo on cooling red warty crystals of neutral hydurilate of copper. This salt is then composed by hot hydrochloric acid, and the hydurilic acid which crystallises out washed with dilute hydrochloric acid and dried over the water-bath.

Properties.—Hydurilic acid prepared as above forms a bulky white powder havin yellowish tinge; by once re-crystallising it from water, it may be obtained quite p and colourless. It is very sparingly soluble in cold *water*, somewhat more in hot wa and crystallises therefrom on cooling in small four-sided prisms containing 4 at. wa $C^8H^6N^4O^6.4H^2O$. It is also but very slightly soluble in *alcohol*, which, however, d not precipitate it from the aqueous solution.—*Sulphuric acid* dissolves it without composition, and on adding water, part of the hydurilic acid separates out again. *hydrochloric acid* it is even less soluble than in water, and is gradually precipita by it from the aqueous solution. From a hot concentrated solution in hydrochl acid, or from an ammoniacal solution decomposed by hydrochloric acid, it separ as a crystalline powder consisting of rhombic tablets containing 2 at. water of cr tallisation: $C^8H^6N^4O^6.2H^2O$. The water, amounting to 6·86 per cent. (2 at. = 6 is given off at 140°.

Hydurilic acid bears a tolerably high temperature without decomposition; it li wise offers considerable resistance to the action of *alkalis*, being attacked but slo and without blackening, by melting potash, with formation of oxalic acid. It is attacked by reducing agents; but *oxidising agents*, such as *chlorine*, *bromine*, *nitric a oxide of silver*, *peroxide of lead*, and *sesquichloride of iron*, attack it very quic yielding various products. When heated with *ferric chloride*, it yields oxy

Digitized by Google

durilic acid, an acid not yet examined, but characterised by the blood-red colour which it produces with ferric salts. With a mixture of *hydrochloric acid and chlorate of potassium*, hydurilic acid yields dichloro-hydurilic acid, $C^8H^4Cl^2N^4O^6$.—Fuming *nitric acid* converts it into alloxan without any other product; but with nitric acid of ordinary strength, it yields alloxan together with violuric acid, violantin and dilituric acid (ii. 965). If the action be carried on to the end, with aid of heat, the only product is dilituric acid*; but if it be interrupted at an earlier stage, a mixture is obtained, varying in composition according to the duration of the action:

$$\underset{\text{Hydurilic acid.}}{C^8H^6N^4O^6} + NHO^3 = \underset{\text{Violuric acid.}}{C^4H^3N^3O^4} + \underset{\text{Alloxan.}}{C^4H^3N^2O^4} + H^2O;$$

$$\underset{\text{Hydurilic acid.}}{C^8H^6N^4O^6} + 2NHO^3 = \underset{\text{Dilituric acid.}}{C^4H^3N^3O^5} + \underset{\text{Alloxan.}}{C^4H^3N^2O^4} + NHO^2 + H^2O.$$

Dilituric acid may indeed be regarded as a product of the oxidation of violuric acid, $C^4H^3N^3O^5 = C^4H^3N^3O^4 + O$; and violantin, $C^8H^6N^6O^8$, is a compound of the two. With *nitrous acid*, the same products are obtained. With nitrite of potassium and excess of nitrous acid, the products are violurate of potassium and alloxan:

$$\underset{\text{Hydurilic acid.}}{C^8H^6N^4O^6} + NKO^2 + 2NHO^2 = \underset{\text{Violurate of potassium.}}{C^4H^2KN^3O^4} + \underset{\text{Alloxan.}}{C^4H^3N^2O^4} + 2H^2O + 2NO$$

Hydurilic acid is most distinctly characterised by the splendid dark-green colour which the acid and its salts produce in a solution of *ferric chloride*. The colour is destroyed by strong acids and alkalis, also by heat, the hydurilic acid then decomposing and the colour changing to red. Characteristic also are the chalk-white precipitates produced on adding hydrochloric acid to the alkaline solution, and the reactions with hydrochloric acid and chlorate of potassium and with nitric acid, just mentioned.

Hydurilates. Hydurilic acid is dibasic, yielding both acid and neutral salts. It dissolves easily in ammonia, potash, and soda, forming moderately soluble salts; the other hydurilates are sparingly soluble or insoluble. These salts cannot, however, in general be obtained by double decomposition, since the acid has a great tendency to form double salts; they must therefore be prepared with the free acid. The acid decomposes most metallic chlorides, forming acid salts; also acetates, with formation of neutral salts, excepting in the case of the ammonium- and potassium-salts.

Hydurilates of Ammonium.—The *acid salt*, $C^8H^5(NH^4)N^4O^6$, obtained by heating dialuric acid in glycerin (p. 220), is nearly pure, having only a faint yellowish colour. It is moderately soluble in boiling water, and separates, on cooling, in crusts and granules. By solution in hot dilute ammonia, and precipitation with acetic acid, it is obtained quite pure, in small octahedral crystals, which, however, soon lose their form. Strong acids remove only part of the ammonia. The crystals are anhydrous.

The *neutral-salt*, $C^8H^4(NH^4)^2O^6$, is obtained by mixing the acid salt with ammonia, and separates from a hot saturated solution by rapid cooling in needles containing 2 at. water; it is also obtained in the same form by precipitation with sulphide of ammonium, in which it is insoluble. The solution when left to stand, or slowly evaporated, deposits large shining monoclinic prisms, with dihedral summits, containing 4 at. water, and efflorescing, with loss of water and ammonia, when exposed to the air. (For Rammelsberg's determination of the form of these crystals, see Ann. Ch. Pharm. cxxvii. 19.) The salt is moderately soluble in water, very easily in ammonia, and is completely precipitated therefrom by alcohol in amorphous flocks or in needles.

Hydurilate of Barium (neutral), $C^8H^4Ba''N^4O^6.2H^2O$, is obtained as an amorphous precipitate, which soon becomes crystalline, on adding a hot solution of hydurilic acid to acetate of barium.

Hydurilates of Calcium.—The *acid salt*, $C^{16}H^{10}Ca''N^8O^{12}.16H^2O$, separates, on adding hydurilic acid to a solution of chloride of calcium, in small shining prisms, insoluble in water. The *neutral salt*, $C^8H^4Ca''N^4O^6.6H^2O$, is obtained by decomposing acetate of calcium with hydurilic acid, as an amorphous precipitate, which becomes crystalline on standing. It gives off 2 at. water at 130°.

Hydurilates of Copper.—The *acid salt*, $C^{16}H^{10}Cu''N^8O^{12}.16H^2O$, is obtained by adding cupric acetate to excess of hydurilic acid, or by mixing the acid with cupric sulphate. From concentrated solutions it separates in green needles; from more dilute solutions, in thin prisms of a shining yellow colour. It is decomposed by excess of

* Schlieper's "nitro-hydurilic acid," obtained by the action of hot nitric acid on hydurilic acid, was most probably dilituric acid containing potash, derived from the impure hydurilic acid used. (Baeyer, Ann. Ch. Pharm cxxvii. 211.)

Digitized by Google

strong acids. When heated, it gives off the whole of its water, and is converted a red powder of the anhydrous salt, which is also precipitated immediately from solutions.

The *neutral salt*, $C^8H^4Cu''N^4O^6.8H^2O$, is obtained by adding hydurilic acid to ex of cupric acetate, or by mixing the neutral ammonium- or sodium-salt with cu sulphate. Cold dilute solutions yield a red precipitate of the hydrated salt, consis of short needles; warm concentrated solutions, a dark brown-red precipitate of anhydrous salt. The red salt is converted by heat into the brown salt, giving off water, but recovers it in contact in water. The salt is decomposed by excess of hy chloric acid, yielding hydurilic acid and chloride of copper.

Hydurilates of Iron.—The ferric salt is a dark green, easily decomposible cipitate; the *ferrous salt* is a white precipitate which soon turns green.

Hydurilate of Lead is a white precipitate, insoluble in acetic acid, insolubl water, soluble in nitric acid; obtained by adding hydurilic acid to neutral ace of lead.

Hydurilate of Potassium has not been obtained in definite form. A solutio hydurilic acid in potash mixed with acetic acid, yields hydurilic acid contain variable quantities of potash; alcohol also throws down from the same solutio substance containing more potash than the neutral salt would contain.

Hydurilate of Silver.—Acetate of silver forms with hydurilic acid small shin prisms, which soon turn grey: with a cold solution of hydurilate of ammonium forms a white precipitate; with a warm solution, crystals which soon turn black. boiling the silver-salt with water, silver is reduced, and the hydurilic acid is oxidi forming oxyhydurilic acid (p. 221).

Hydurilate of Sodium, $C^8H^4Na^2N^4O^6.H^2O$, is obtained by acidulating a solut of hydurilic acid in strong soda-ley with acetic acid, and adding alcohol. The neu salt then separates in small, colourless, shining prisms, which are moderately solu in cold, easily in hot water. The acid-salt does not appear to exist.

Hydurilates of Zinc.—The *acid salt*, $C^{16}H^{10}Zn''N^8O^{12}$, crystallises from a solut of zinc-chloride mixed with hydurilic acid, in beautiful feathery groups of need having a strong lustre. The *neutral salt*, $C^8H^4Zn''N^4O^6.4H^2O$, separates on mix hydurilic acid with excess of zinc-solution, as a white amorphous precipitate, wh soon becomes crystalline.

Dichlorohydurilic acid. $C^8H^4Cl^2N^4O^6$.—This compound is prepared on add chlorate of potassium by small portions, and with constant stirring, to a pasty mixture hydurilic and strong hydrochloric acid. A snow-white powder is thus obtained, which very slightly soluble in water, either hot or cold, and is most easily purified by dissolv it in strong sulphuric acid, which exerts but little action on it, but thickens when hea with it over the water-bath, and, on gradual addition of water, deposits the chlorina acid in small rhombic crystals, containing $C^8H^4Cl^2N^4O^6.4H^2O$. It is especially p manent in acid liquids, is not attacked by chlorine, and but slowly by warm ni acid, with formation of dilituric acid, but is easily decomposed by alkalis.

Dichlorohydurilic acid is a strong dibasic acid, which dissolves in alkalis, especia with aid of heat, and is reprecipitated by hydrochloric acid. The solutions turn on boiling, yielding a metallic chloride, and an acid not yet examined.

The *neutral potassium-salt*, $C^8H^2K^2Cl^2N^4O^6.4H^2O$, crystallises from a warm solut of potash saturated with the acid in small, beautiful six-sided tables. It dissol sparingly in cold, more readily in hot water. It retains its water of crystallisation 120°; at a stronger heat it turns red and decomposes.

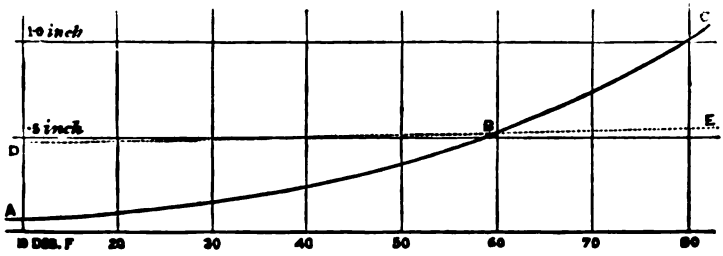
HYGRINE. (Wöhler and Lossen, Ann. Ch. Pharm. cxxi. 374.—Loss *Dissertation.*)—An organic base occurring, together with cocaïne, in coca-lea (i. 1059). To extract the two bases, the leaves are exhausted with rain-water a temperature of 60° to 80°; the united extracts are precipitated with neutral acetate lead and filtered; the filtrate is precipitated with a saturated aqueous solution sulphate of sodium, again filtered and concentrated; and the concentrated liquid, af being rendered slightly alkaline by carbonate of sodium, is agitated four or six tir with ether to extract the cocaïne. The remaining liquid mixed with an additio quantity of carbonate of sodium, and again shaken with ether, yields hygrine an neutral oil having the odour of tobacco. These substances remain when the ether distilled off; and on further heating the residue, till it boils, the temperature quic rises to above 280°, and a brown alkaline oil distils over, while a black resin is behind. When the distillate is maintained at 140°, for some hours, in a stream hydrogen, the greater part passes over of a yellow colour (*a*), while the remain volatilises only at 140° to 230°, and condenses to a thick brown oil (*b*). Hygrine contained in both portions; that in *b*, however, is contaminated with a neutral

Digitized by Google

that in *a* with an easily volatilised substance. To remove a little ammonia present, *a* is converted into oxalate, the salt is dissolved in absolute alcohol, the solution evaporated, and the residue mixed with caustic potash, which separates the hygrine in the form of oil. The alkaline solution is heated to boiling in a stream of hydrogen, when the hygrine, dissolved in the water, passes over (by adding water to the residue and again distilling to dryness, a further quantity may be obtained), and is extracted from the distillate by ether; on again distilling the ethereal solution, the hygrine remains behind. The neutral oil in *b* is removed by dissolving *b* in water containing hydrochloric acid, shaking the solution with ether, and separating the ethereal layer; after which, the acid solution is supersaturated with caustic soda, and the hygrine taken up by ether, as in the treatment of *a*. (Lossen.)

Hygrine is a thick, pale-yellow oil, having a strong alkaline reaction, a burning taste, and an odour of trimethylamine. It produces white clouds with the volatile acids; distils very slowly with vapour of water. It does not appear to be poisonous.

Hygrine does not dissolve in *water* in all proportions. The aqueous solution forms a white precipitate with *dichloride of tin*, yellowish with *sulphate of iron*, light blue with *sulphate of copper;* on boiling the solution, the copper precipitate becomes granular, but not brown. Hygrine forms white precipitates with *chloride of mercury* and *nitrate of silver;* the silver precipitate quickly turns brown.



Hygrine combines with *hydrochloric acid*, forming deliquescent crystals. The aqueous hydrochlorate forms a brown flocculent precipitate with *di-iodide of potassium*, red-white with *dichloride of tin*, white with *corrosive sublimate*, partly flocculent and partly in oily drops. With *tetrachloride of platinum* it forms dirty white-yellow (or red) flakes, which are decomposed by heating the liquid, and do not appear in very dilute solutions. *Picric acid* throws down from hydrochlorate of hygrine a yellow powder; *gallotannic acid*, a white precipitate.

Hygrine dissolves in *alcohol* and in *ether*.

HYGROMETER. HYGROMETRY. A Hygrometer (*hygrós*, moist; *métron*, measure) is any instrument which measures the amount or degree of moisture in the atmosphere. There are, however, several kinds of hygrometers which measure, or are said to measure moisture, by entirely different modes, and the problem itself—to estimate the degree of moistness of the air—is found on examination to be quite ambiguous. It is therefore necessary to attend to the principles of the subject.

Principles of Hygrometry.—Water, both liquid and solid, always tends to assume the gaseous form, and in so doing exerts an elastic force increasing as the temperature rises. In *fig.* 565 the curve ABC is drawn so as to represent the law of the elastic force of aqueous vapour: if the divisions along the horizontal axis represent the tem-

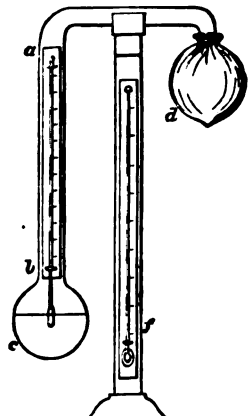
Fig. 565.

perature of the water in degrees Fahr., the perpendicular lines drawn from them to the curve, being measured, will give the corresponding force of its vapour estimated in the height of the column of mercury which it would be able to sustain.

The elastic force obviously increases in a higher ratio than the temperature, and, in order that such increasing force may be exerted when water is confined in a given space, it is necessary that a larger and larger quantity of water should become vapour. It is true that if the weight of vapour be not increased, its elastic force will rise with its temperature, but in a much less ratio. For aqueous vapour, like any other gas, tends to expand by $\frac{1}{491}$th part of its volume at 32° F. for every degree of increased temperature. Thus, if the vapour which rises from water at the temperature of 60° F. and has the elastic force of ·518 inch be confined in the same space, but apart from water, and heated, its elastic force will rise in a manner represented by the straight line BE (*fig.* 565); but if more water be present to supply additional vapour, the elastic force of the whole vapour would rise, as shown by the curve BC.

Digitized by Google

On the other hand, if the vapour at 60° F. be cooled, it will, as a gas, tend to exert an elastic force falling as the straight line BD. But the elastic force which liquid water exerts falls more rapidly, as shown by the curve BA; hence part of the vapour must be condensed to the liquid condition until the elastic force of the remainder is not greater than that which rises from water at that temperature. The following definitions will now be understood. Aqueous vapour is said to be *saturated*, and of *maximum elastic force*, when any reduction of temperature, or any increase of pressure, would cause some of the vapour to be condensed. The temperature of saturated vapour is said to be at the dew-point. Thus aqueous vapour of 60° F. and of an elastic force of ·518 inch is saturated, and 60° is its dew-point. Any portion of aqueous vapour has a dew-point; for the temperature may always be reduced so low that a portion will be condensed by any further reduction.



What is true of aqueous vapour alone is also true of aqueous vapour mixed with air: for it is a law that mixed gases do not exert their pressure upon each other. The only difference is, that vapour does not spread so rapidly into a space occupied by air as it does into a vacuous space. In an *indefinitely small space*, then, the vapour and air may be considered perfectly independent of each other. The larger the volume, the longer do we need to wait until diffusion has produced perfect mixture.* Air is said to be saturated with moisture when the aqueous vapour it contains is of maximum elastic force. The temperature of the air is then called its dew-point—for any reduction of temperature would cause the condensation of some vapour in the form of *dew* particles.

The *degree of humidity*, or *of saturation*, is the ratio which the vapour in the air bears to what it might contain. (See HEAT, pp. 81, 83.)

Condensing Hygrometers are those which, by cooling the air until the contained vapour begins to be condensed, indicate the dew-point, and thus enable us to learn the elastic force of the vapour. Dalton first proposed this method of Hygrometry, using a cup of cold water. Le Roi proposed the use of ice for this purpose; and in the absence of any hygrometer, the dew-point may be ascertained very accurately, by exposing to the air a small bright metal cup, for instance a platinum crucible, containing water cooled by ice or by some salt, such as sal-ammoniac or nitrate of ammonium, dissolved in it. The water is to be stirred with the bulb of a small thermometer, and the degree noted at which dew begins to form or to evaporate on the bright metallic surface.

Daniell's *Hygrometer* was the first accurate instrument invented, and may still be used to determine the dew-point with considerable ease and exactness (*Daniell's Meteorological Essays*, p. 127). It consists (*fig.* 566) of a small glass siphon, at each end of which is a thin glass bulb about 1¼ inch in diameter. The longer leg *ab* is about 4 inches long and contains a small but very delicate thermometer, the bulb of which is within the terminal glass ball. The siphon contains so much common ether as when poured into the lower bulb *c* will rather more than half cover the enclosed thermometer-bulb. Before the tube is sealed up, the ether is boiled, so as to drive out the whole of the air. The essential part of the instrument is completed by covering the upper bulb *d* with muslin and gilding a part of the lower bulb. It is now usual, however, to make this lower bulb of black glass. The siphon-tube is placed for use upon the little stand which contains the second thermometer *f*, in order that the temperature of the air may be observed at the same time as its dew-point.

Fig. 566.

To make an observation, all the ether within the instrument is first poured into the lower bulb. Then taking a bottle of common ether, a few drops are poured upon the muslin of the upper bulb. Its evaporation cools the bulb and condenses the ether vapour within. Fresh vapour flows along the bent tube from the lower bulb, and, in the manner of Wollaston's *cryophorus*, the temperature of this lower bulb is gradually reduced, until the dew-point of the surrounding air is reached, and dew may be observed forming upon the gilded or blackened surface of the bulb. The dew-point, as shown by the included thermometer, is then to be read, but accuracy is only to be attained by observing several successive depositions

* A neglect of this fact has led many eminent meteorologists to consider the atmosphere as composed of two independent atmospheres, namely of aqueous vapour and of the other gases. Nothing can be more erroneous.

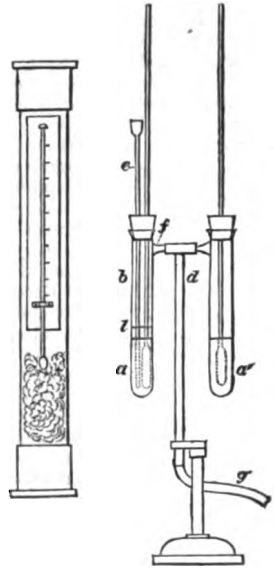
and evaporations of dew in a manner fully described under the head of Regnault's Hygrometer.



The hygrometer of Daniell, however elegant and pleasing in theory, has many sources of inconvenience and inaccuracy. The expenditure of ether is considerable and costly, and in a hot and dry climate it is very difficult to obtain any deposition of dew, during the long-continued manipulation and close observation of the instrument which is always necessary. The warmth and moisture of the hand and body are sure to affect the indications of both thermometers. The cold ether vapour flowing from the upper bulb may also cause inaccuracy. The last and most important objection is that cold is produced only at the surface of the ether in the lower bulb, and there is no agitation of the liquid to ensure uniformity of temperature. Hence the internal thermometer may often indicate a temperature some degrees different from that at which dew is being deposited. This objection is partially remedied by making the lower bulb oblique, so that one part of it shall be nearly in contact with the thermometer-bulb within. Daniell, well aware of this objection, remarks that dew will first be deposited in a circle round the bulb near to the surface of the ether, and directs that the thermometer-bulb shall be placed so as to be cut by the surface of the ether.

Subsequent to Daniell's invention, several dew-point instruments were devised, in which the evaporation of ether was made to cool the bulb of a thermometer and cause a deposit of dew, either upon the bulb or a metallic capsule in a more simple manner. Such is that of Jones (Phil. Trans. [1826] cxvi. pt. ii. 53). Of a similar nature are the *hygromètre à capsule* and the *hygromètre à virole d'or* of Pouillet (Élém. de. Phys. [7th ed. 1856] ii. 739). That of M. Belli (Ann. Ch. Phys. [3] xv. 506) is different and very ingenious, giving a continual indication of the dew-point.

Connell's *Hygrometer*, very lately proposed, and to some extent, we believe, brought into use, consists of a thermometer with its bulb immersed in ether, contained within a small metal globe. A common exhausting syringe is used to cause the evaporation of the ether, and the dew-point is then ascertained, exactly as in Daniell's or Regnault's hygrometer. This method presents some slight advantages over Daniell's, but retains all its worst causes of error and inconvenience. It is also an expensive instrument, and cannot compare with Regnault's Condenser Hygrometer either in theory or in practice. It is described in the Transactions of the Royal Society of Edinburgh xxi., and Phil. Mag. [4] viii. 81.

Dr. George Cumming's *Hygrometer* (Quar. Jour. of Sci. &c. 1828, Jan. to June, p. 403) seems first to have introduced a method now finally adopted as the best. It consisted (*fig.* 567) of a thin glass or metallic tube containing a delicate thermometer enveloped in sponge or other porous substance, upon which a little ether was to be poured. Almost any degree of artificial cold could then be produced by a stream of air from a pair of bellows, or other pneumatic contrivance. The only important objection to this instrument is the presence of a spongy or porous substance, which would prevent perfect uniformity of temperature within the tube.

Fig. 567. *Fig.* 568.

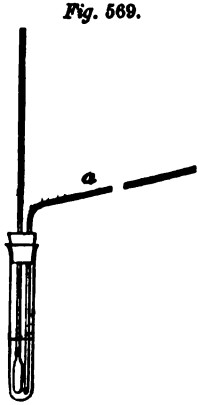
Döbereiner further proposed a hygrometer in which a current of air from a forcing pump is made to traverse the ether, disposed as in Daniell's instrument, and thus produce cold by evaporation. (Pogg. Ann. lxv. 339.)

Regnault's *Condenser Hygrometer* (Ann. Ch. Phys. [3] xv. 129) may be described as a perfect instrument of its kind. In its complete form (*fig.* 568) it consists of a very thin and brightly polished silver thimble *a*, 45 mm. high and 20 mm. in diameter, fitted to the glass tube *b*, which again is fixed by the small lateral tube *t*, and the metallic tube *d*, to the stand. The upper end of the glass tube *b* is closed by a cork, bearing a thin glass tube *e*, descending nearly to the bottom of the silver thimble, and a very delicate and accurate thermometer, the pear-shaped bulb of which is in the centre of the thimble. A second exactly similar thermometer, similarly placed within a glass tube and silver thimble, is mounted on the other side of the stand, but the cork is not penetrated by any glass tube.

To make an observation, so much good ether is poured into the tube *b* as will rather

Digitized by Google

more than fill the thimble to the level *l*, and the cork being fitted in air tight, the instrument is put in connection, by means of the caoutchouc tube *g*, with a common aspirator, by which an exactly regulated flow of air through the instrument may be obtained. The aspirator, which may have a capacity of 3 or 4 litres (3 or 4 quarts) is placed close to the observer, and the hygrometer may be at some distance, for instance outside a window, being observed, if necessary, with a telescope.



Now when water is allowed to flow from the aspirator, air is drawn through the tube, and bubbling up through the ether, causes a more or less rapid evaporation. The temperature of the ether is thus slowly reduced, and from its constant agitation by the stream of air, the silver thimble and the thermometer-bulb are maintained at an exactly similar temperature. After a minute or two at the most, dew will begin to form on the thimble and will be very visible on its brightly polished surface. The thermometer is instantly to be read, and the stream from the aspirator to be stopped. Suppose that the reading observed is 48·1° F., the deposit of dew may increase for a few moments, but will soon begin to evaporate again, the thermometer rising. At the moment that the dew entirely disappears, read the thermometer again; let it be 49·3. Considering that dew requires a short time to form or evaporate in a visible degree, it is obvious that the dew-point lies between 48·1 and 49·3. Let an exceedingly slow current of air be now drawn through the ether, so that the thermometer is very gradually reduced to 49·2, 49·1, 49·0, and so on. The point at which dew first appears may now be observed with much greater accuracy; let it be 48·8. Still it is probable that 48·8 is somewhat below the exact dew-point. If, when the current is stopped, the small deposit of dew vanishes at 49·0, we may consider the mean, or 48·9, to be the true dew-point; but if necessary we may, by still slower procedure, approximate even more closely. "All these operations," observes M. Regnault, "take more time to describe than to execute; with a little practice, three or four minutes are sufficient for determining the dew-point almost within $\frac{1}{10}$ of a degree Centigrade."

At the same time, the second thermometer is to be read, to give the common temperature of the air. From its parallel circumstances and position, its indications would be exactly similar to those of the other; hence the difference of the two gives the depression of the dew-point free from almost all kinds of error. It is obvious that all the objectionable points in Daniell's hygrometer are avoided in this admirable instrument. The only remaining objection is the inconvenience of keeping or carrying about a large aspirator, and frequently filling it with water. In the Kew Observatory, the aspirator is in the form of a circular bellows, to the lower movable board of which a weight is attached. Mr. Welsh also proposed to expand the upper end of the tube *e* into a small funnel by which fresh ether may readily be introduced.

Lieut. Noble has obtained dew with this hygrometer, at all temperatures down to −35°, the limit of graduation of his thermometer, the only requisites when the dew-point is very low being patience and pure ether. (Phil. Mag. [4] xi. 305.)

Several London instrument-makers have rendered this instrument less expensive by omitting the second thermometer and its appendages. They have likewise substituted a closed tube of black glass for the polished silver thimble. This is, on the whole, an improvement, for the dew is even more visible on the black surface, and the difficulty of maintaining the silver bright is avoided; but on the other hand the uniformity of temperature is not so rigorously ensured. As regards the temperature of the air, we think it is best learnt by an ordinary thermometer freely exposed, and that Regnault's parallel arrangement of the second thermometer, although beautiful in theory, is actually erroneous and undesirable in the ordinary use of the instrument.

Fig. 569.

Except, however, for refined researches or long continued series of observation, a much simpler apparatus will serve. The practical chemist has only to take a common test-tube, containing about 1½ inch depth of ether, insert somewhat loosely a delicate tube-thermometer and glass tube, as shown in *fig.* 569, and gently blow with the mouth through the bent tube *a*, and the whole process of observation can be conducted almost as well as in Regnault's complete instrument. It is necessary to have the tube *a* of considerable length, that the moistness and warmth of the body and the breath may not affect the air surrounding the tube. The writer had used such an apparatus daily for many months before noticing that Regnault mentions its successful use.

Hygrometry by Evaporation.—Dr. Hutton of Edinburgh first suggested that the degree of cold produced by the evaporation of water in the air, would depend upon and therefore indicate the moistness of the air. Leslie again

hygrometer of the meteorological observer, Mr. Glaisher has paid much attention to the perfecting of the instrument in every detail. He has finally adopted a pair of very delicate thermometers (see *fig.* 570) about one foot long, and with small spherical bulbs of thin glass of about ¼ inch diameter. They are mounted upon metal scales graduated from about −10° to +130° F. and fixed parallel to each other from 2 to 4 inches apart upon a metal cross piece. Care is taken that each pair of thermometers is as exactly similar as possible. The bulb of the wet thermometer is covered with thin muslin, round the neck of which is twisted a conducting thread of lamp-wick, common darning cotton, or floss silk; this passes into an adjacent vessel of water placed about three inches distant from the wet bulb, a little beneath it, and on the opposite side to the dry-bulb thermometer. It is a very objectionable practice to place a long glass cistern between the two thermometers; for the water will seldom be of exactly the same temperature as the surrounding air, and will tend slightly to vitiate the readings of both thermometers. The writer prefers for a cistern a short narrow-necked glass bottle, from which but little evaporation will take place. The water must be either rain or distilled water. Care must be taken never to record any readings when the bulb is not thoroughly moist all over. As dust and saline particles gradually settle on the wet muslin, it is well to re-cover the bulb and supply a fresh wick about every month. Before use, too, each wick should be washed in a solution of carbonate of soda, and pressed whilst under water throughout its length. The supply of water to the bulb can be easily regulated by raising or lowering the cistern.

Fig. 570.

In taking an observation, the dry-bulb thermometer is first to be read, because it is most liable to change; the wet-bulb is then to be read, the two readings to be recorded, and a comparison with the thermometers made, to secure the correct number of whole degrees. The observer must follow the directions under the article THERMOMETER, as regards placing the instrument, correcting the thermometer-readings, &c.

The dry- and wet-bulb hygrometer continues to act even when the water is frozen, since evaporation still takes place; but especial care must be taken that the bulb really is covered with ice, and if not, water must be poured upon it, and the observation delayed till the water be frozen, and the thermometer sink to a constant reading. In frosty weather it is best to wet the bulb after every periodic observation, or at least ten minutes before the next.

Theory of the Psychrometer.—Although we may ascertain the dew-point from readings of the dry- and wet-bulb thermometers on purely experimental grounds, as in using Glaisher's factors, the subject also admits of mathematical investigation. Mr. Ivory first solved the problem (Phil. Mag. [3] lx. 80) with substantial correctness. August of Berlin, and Bohnenberger, showed the coincidence of the theory with experiment, and determined the constants with accuracy (August, *Ueber die Fortschritte der Hygrometrie in der Neuesten Zeit, Berlin*, 1830.—Bohnenberger, *Tubingen Nat. Hist. Soc. Memoirs*, vol. ii.). But the subject is best known in England from Dr. Apjohn's excellent results (Phil. Mag. [3] vi. 182; vii. 266, 470; xiii. 261).

We now give the investigation as it is stated by Regnault after the method of M. August.

The evaporation of a liquid involves the conversion of sensible into latent heat, and the supply of heat must be drawn from the liquid evaporated, from the remaining liquid, or from surrounding objects. When air is in contact with the moistened bulb of a thermometer, the evaporation of the water will reduce the temperature of the bulb, but the fall of temperature will be checked by heat communicated from the remainder of the air. At some point, the amounts of heat subtracted and communicated will be equal, and an invariable temperature of evaporation will be the result.

Let us suppose, with M. August, that the portions of air successively in contact with the moist thermometer-bulb become thereby perfectly saturated with moisture, and are reduced to the temperature of the bulb.

Let w = weight of stratum of dry air surrounding the bulb at 0° C., and under the pressure of 0·760.

h = height of barometer.

t = temperature of surrounding air given by the dry-bulb thermometer.

t' = temperature of evaporation, or the reading of the wet-bulb thermometer.

f and f' = the elastic forces of saturated aqueous vapour for the temperatures t and t'.

x = the actual elastic force of vapour in the air at the time.

Digitized by Google

In the stratum of air surrounding the bulb, the aqueous vapour exerts the elastic force f', and the air consequently exerts the elastic force $h-f'$. The weight of dry air is then

$$w \cdot \frac{1}{1+\alpha t'} \cdot \frac{h-f'}{30},$$

α being the coefficient of expansion of a gas for every degree of temperature. The weight of vapour already in this air is

$$w\delta \cdot \frac{1}{1+\alpha t'} \cdot \frac{x}{30};$$

in which δ represents the specific gravity of aqueous vapour in relation to air. The weight of vapour added by contact with wet bulb similarly is

$$w\delta \cdot \frac{1}{1+\alpha t'} \cdot \frac{f'-x}{30}.$$

Now, if γ be the specific heat of air, the quantity of heat disengaged by the dry air in cooling from t to t' is

$$w \frac{1}{1+\alpha t'} \cdot \frac{h-f'}{30} \cdot (t-t') \cdot \gamma.$$

Similarly k being the specific heat of aqueous vapour, the quantity of heat disengaged by the vapour previously in the air is

$$w\delta \frac{1}{1+\alpha t'} \cdot \frac{x}{30} (t-t') \cdot k.$$

Lastly, let λ be the latent heat absorbed by water, when becoming gaseous between the temperatures t and t'.

The quantity of heat absorbed will be

$$w\delta \frac{1}{1+\alpha t'} \cdot \frac{f'-x}{30} \cdot \lambda.$$

Now when the temperature of evaporation is constant, this heat absorbed in evaporation must be equal to that given out by the air and the other portion of vapour; or we have, by equating them and striking out the factor $w \cdot \frac{1}{1+\alpha t'} \cdot \frac{1}{30}$,

$$\gamma(h-f')(t-t') + \delta k x (t-t') = \delta\lambda(f'-x);$$

whence

$$x = \frac{1 + \frac{\gamma}{\delta\lambda}(t-t')}{1 + \frac{k}{\lambda}(t-t')} f' - \frac{\frac{\gamma}{\delta\lambda}(t-t')}{1+\frac{k}{\lambda}(t-t')} \cdot h.$$

Inserting values of the known quantities, namely, for γ, 0·2669, for k, 0·2669 (the specific heat of aqueous vapour being assumed equal to that of air), for δ, the specific gravity of aqueous vapour, 0·6235, and for λ, the latent heat of aqueous vapour, $640 - t'$, according to the law of Watt, and neglecting some of the smaller terms, August obtains the formula $x = f' - \frac{0{\cdot}568\,(t-t')}{640-t'} \cdot h$, the temperatures being expressed in centigrade degrees.

Regnault, using more accurate data, namely, for δ, 0·622, and for λ, $610 - t'$ ($\gamma = k = 0{\cdot}2669$ as before), modifies this to

$$x = f' - \frac{0{\cdot}429\,(t-t')}{610-t'} \cdot h.$$

Experimentally, Regnault has found that the formula $x = f' - \frac{0{\cdot}480\,(t-t')}{610-t'} \cdot h$ gives an almost perfect coincidence between the calculated and true results, when the air is not more than $\frac{1}{10}$ saturated. Otherwise the first coefficient 0·429 is to be preferred.

The formula which has been most used in the reduction of dry- and wet-bulb observations is that obtained by Dr. Apjohn. In the Greenwich observations it is given as follows:

$$F = f - \frac{d}{88} \cdot \frac{h}{30} \qquad F = f - \frac{d}{96} \cdot \frac{h}{30}$$

The first formula is to be used when the reading of the wet-bulb is above 32° F., and the second when below. In the above, d is the difference of the dry- and wet-bulb readings, h the height of the barometer, f the elastic force of vapour for the temperature of the *wet-bulb*, to be taken from Table II., and F the elastic force of vapour at the dew-point, from which the dew-point may be found, if necessary, by the table.

Digitized by Google

From a statement in *Daniell's Meteorology* [Essays, 1856] ii. 100, it would seem the errors of results obtained by Apjohn's formula, lie within closer limits than obtained by Glaisher's factors.

Taking the expression in the form

$$F = f - m.d.\frac{h-f}{30},$$

the term with $\frac{f}{30}$ being inconsiderable except at great heights, the following of the coefficient m have been given (for degrees Fahr.):

The supposed great accuracy of many of these determinations has been some shaken by the later experiments of Regnault (Ann. Ch. Phys. [3] xv.), f finds that the temperature of evaporation is not invariable, but sinks lower, the gr the rapidity with which the air surrounding the wet bulb is moving. He is thu to doubt the soundness of August's assumption, that the stratum of air surroundin wet bulb is always saturated and of the same temperature as the bulb, and he cons that the radiant heat falling on the bulb is an element not to be neglected. ordinary formulæ, however, may be considered sufficiently accurate as long a velocity of the air does not exceed 5 or 6 metres (16 to 20 feet) per second.

We quite agree, however, with Dr. Drew ("Practical Meteorology," p. 169), tha problem of the dry- and wet-bulb thermometers is still quite open to fresh investig

Hygrometric Calculations.—Having found the dew-point of the air, usually required to deduce other data concerning the moistness of the air. necessary calculations are a little intricate, but have been brought to a very satisfa state of accuracy by Mr. Glaisher, whose excellent hygrometrical tables for the and wet-bulb thermometers, give all the necessary deductions from the readin the thermometers, almost without calculation. These tables are quite indispensab any person who has frequently to make hygrometrical calculations, but the inge hygrometric sliding rule of Mr. Welsh (Brit. Assoc. 1851; Trans. Sec. p. 42 manufactured by Adie, will also give most of the required results mechanically. can here only enter the subject briefly.

The elastic force of aqueous vapour in the air is the same as the maximum el force at the dew-point, and we, therefore, ascertain it by referring to the temper of the dew-point in a table of the maximum elastic force of vapour. The follo table (II.), having been calculated from the experimental results of Regnault, i most reliable of the kind.

If there be a fractional part of a degree over, multiply it into the next following *d ence* in the third column (dividing by 10 if a decimal), and add the result t number opposite the whole degree.

This table differs somewhat from that adopted by the Royal Society in "Report on Physics" (p. 89), and from several others calculated from older and trustworthy experiments than those of Regnault.

To find the weight of a cubic foot of aqueous vapour of maximum tension at temperature t, let E_t be the elastic force at that temperature. Then since 25 grains is the weight of a cubic foot of vapour at 212°, of an elastic force of 30 in 258·448 grains $\times \frac{E}{30}$ would be the weight of a cubic foot of the vapour saturate temperature t, after it has been heated up to 212° and kept under the same pre E_t as before. Since a gas expands 0·3665 of its own volume from 32° to 212 0·0020361 for each degree Fahr.,

$$258{\cdot}448 \text{ grains} \times \frac{E_t}{30} \times \frac{1{\cdot}3665}{1 + {\cdot}0020361 \times (t - 32°)}$$

will be the weight of a cubic foot of vapour saturated at the temperature t. From formula, the numbers in Table III. (p. 232), column 2, were obtained.

When the air is saturated with vapour and the temperature of the air of evapor and of the dew-point coincide, the required weight of vapour in a cubic foot of air

us one cubic foot of dry air, after becoming saturated with moisture, expands into the ume $\frac{1}{1-\frac{E_t}{p}}$ if it be confined under the same pressure as before.

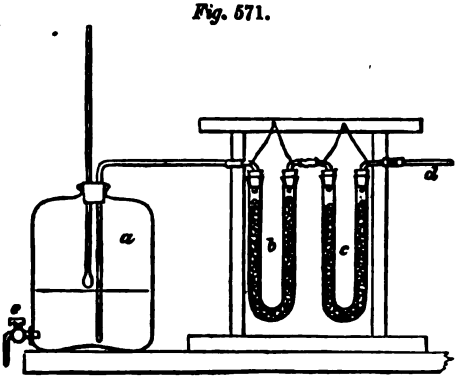
We may now find the weight of a cubic foot of air saturated with aqueous vapour at y temperature: for it is obviously

Veight of cubic foot of dry air + weight of cubic foot of vapour) $\times \frac{p-E_t}{p}$.

Thus are obtained the numbers in column 4 of Table III. When the dry- and wet-lb thermometers read alike, we have at once the weight of a cubic foot of the nosphere for the barometric pressure of 30 inches. For any other height of the rometer we must multiply by this height in inches and divide by 30. When the r is not saturated, we must subtract the following:

$$\left\{\begin{matrix}\text{Weight of cub.}\\ \text{ft. of dry air}\end{matrix}\right\} - \left\{\begin{matrix}\text{weight of cub. ft.}\\ \text{of saturated air}\end{matrix}\right\} \times \frac{\text{Weight of cubic foot of vapour at dew-point}}{\text{Weight of cubic foot of vapour at temperature of air:}}$$

om the weight of a cubic foot of dry air, and reduce the result as before to the rometric pressure at the time.



The Degree of Humidity represents the proportional saturation of the air with isture, decimally expressed, so that saturated air has the degree 100, and perfectly y air the degree 0. It is found by dividing the weight of vapour (Table III. lumn 2) at the dew-point by the weight which would be present at the temperature the air, if it were saturated. Some writers use the corresponding elastic forces of e vapours at the dew-point and temperature of the air (Table II.) in place of the ights of vapour, but the results are nearly the same.

Chemical Method of Hygrometry. The chemist may always avoid the fficulties attending the use of hygrometers, by absorbing the aqueous vapour from

Digitized by Google

any given volume of air and actually weighing it upon the chemical balance. The necessary apparatus (*fig.* 671) consists of a common aspirator *a* and two U-shaped drying tubes *b*, *c*, containing fragments of pumice-stone soaked in strong sulphuric acid. The aspirator being full of water, the second tube *c* is detached, weighed accurately, and again attached on one side to the other drying tube *b*, on the other side to a long *perfectly dry* tube *d*, by means of which air from any required point, as for instance from the open atmosphere outside the laboratory window, may be drawn through the apparatus.

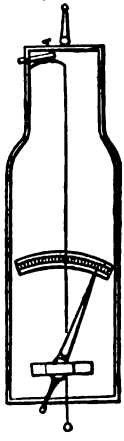
Fig. 671.

The fixed drying tube *b* is employed to prevent any vapour passing back from the aspirator. Regnault took great pains to ascertain the least necessary size of the weighed drying tube. He generally indeed employed two weighed tubes, each 0·18 metre in height, filled with *large* fragments of pumice-stone. But the second tube *rarely* gained 1 or 2 milligrammes in weight, and chiefly served to afford a proof that the absorption by the first tube was complete. It is probably best therefore to dispense with a second weighed tube, as the increased error in weighing the larger apparatus will probably be greater than the minute weight of vapour which may be lost. Additional accuracy may always be had by increasing the volume of air passed through the tube.

A determinate volume of water having been allowed to flow slowly and uniformly from the aspirator by the tap *e*, an equal volume of air, of course, passes through the tube *c*, and becomes desiccated. The weight of vapour absorbed is learnt by again weighing the tube *c*, but to determine the corresponding weight of air with accuracy, we must read the temperature at the end of the experiment by a thermometer placed in the centre of the aspirator, and likewise observe the barometer, then performing the calculation as directed on page 230.

This method may also be used to determine the amount of water *suspended* in the air in the form of mist or cloud. The weight of the watery particles is the excess of the whole weight absorbed over the maximum weight of vapour (saturated) as given in Table III. column 2.

The chemical determination of vapour has been fully considered by Brunner. (Ann. Ch. Phys. [3] iii. 309.)



The chemical method might obviously be used to determine the average amount of vapour in the air during any period of time. It is only necessary for this purpose that a perfectly uniform stream of air pass through the drying tube throughout the period. The total weight of vapour absorbed, divided by the total weight of air passed through, gives the required result. Such a process was proposed by Dr. Andrews (Brit. Assoc. 1851, Trans. of Sec. p. 29), who has also described an aspirator suitable for the purpose (Phil. Mag. [4] iv. 330), and we know not why it is not adopted, at least in some of the principal observatories.

Hygroscopic bodies. Most organised structures expand or contract according to their state of moisture or dryness, and many organic substances to such a degree that they afford very delicate indications of hygrometric changes. Thus a thin shaving of whalebone laid on the hand instantly curls up, and a slip of whalebone furnished with a multiplying index formed the hygrometer finally adopted by Deluc (Phil. Trans. [1791] lxxxi. 419). An ivory hygrometer was also constructed by Deluc (Phil. Trans. [1773] p. 404) and Leslie (Ann. Ch. Ph. i. 468). A hygroscope formed of pieces of deal-wood was designed in 1676 by John Coniers (Phil. Trans. xi. 715). Chimney ornaments are often seen in which certain figures are caused to move by the contraction or expansion of catgut, thus indicating the approach of rain or fine weather. The awn of the *Andropagon contortum* has been used for similar purposes by Capt. Kater; the awn of the *Avena fatua*, or wild oat, by Hooke; the internal membrane of the *Arundo Phragmites*, or common reed, by Adie; and the *Funaria hygrometrica*, or common cord-moss, the arista of the seed of the *Stipa pennita*, or common feather-grass, by others. The hygroscope usually placed at the top of the common barometer or weather-glass consists of an awn or vegetable filament which in twisting or untwisting moves a light index.

Saussure's Hair Hygrometer is the only instrument of this class which has been supposed in late years to possess any scientific accuracy or importance. To construct it, long, soft and straight human hairs must be procured and boiled for half an hour in a litre of water containing 10 grammes of crystallised carbonate of soda. After being well washed in pure water and dried without heat, the best hair is chosen, of a length of about 24 centimetres. One end is fixed to the top of the instrument (*fig.* 572), and the other, being passed round a pulley of the diameter of 6 millimetres, is attached to a weight of about 0·2 gramme (3 grains). An index fixed to the pulley moves over a divided circle, the divisions of which are determined by placing the instrument first over water and then over sulphuric acid, that is in perfectly moist and perfectly dry air, and dividing the space which the index is thus caused to move over into 100 equal parts. When well and delicately constructed, such an instrument will promptly show the slightest changes of moisture in the air.

Fig. 572.

Regnault, in his "Etudes de l'Hygrométrie," has spent much labour and ingenuity in trying to render the Hair Hygrometer scientifically useful. He has only succeeded in showing that two of these instruments will give very different results, if there exists the slightest difference in the nature of the hairs, their preparation, or the weight by which they are extended; that the most carefully constructed instruments are but little accordant; and that, after all, the degrees are quite arbitrary, and can only be reduced to true degrees of humidity or force of aqueous vapour, by a table specially determined by experiment for each instrument. Such a table may be found in Pouillet's *Elements de Physique*, 7th ed. ii. p. 742, having been prepared by Gay-Lussac, and supposed by him to apply to all Hair Hygrometers.

Regnault, indeed, has found that the zero of the Hair Hygrometer, at which it should stand in perfectly dry air, is quite illusory, for the hair will continue to shrink more or less even when it has been exposed for some months to the dry air. He therefore commences the graduation for air about ½ saturated, or of 20 degrees of humidity.

Kæmtz (*Météorologie*, Paris, 1858, p. 74) compares the table of Gay-Lussac with others calculated for Saussure's Hygrometer by Prinsep, Melloni, and August. There is very little accordance.

A great number of experiments on hygroscopes and hygroscopic substances are given in the three elaborate papers by Deluc in the Philosophical Transactions (1773 and 1791), and he says (Ph. Trans. [1791] lxxxi. 40), "I have concentrated in these pages an account of twenty years' assiduous labours in *hygrometry*, mostly occasioned by the anomalies of the *hygroscopic threads*."

There is a complete and learned history of hygrometry by Suerman, entitled "Commentatio de definiendâ Quantitate Vaporis aquei in Atmosphærâ," 4to. Lugd. Bat. 1831.

In Prof. Forbes' *Supplementary Report on Meteorology* (Brit. Assoc. Report, 1840. pp. 95–101) is an excellent *résumé* of the theory of the wet-bulb thermometer.

A general account of hygrometry, with examples of the calculations required in meteorology, is to be found in Dr. Drew's *Practical Meteorology*. W. S. J.

HYOCHOLALIC ACID. Syn. with Hyocholic Acid.

HYOCHOLIC ACID. $C^{36}H^{40}O^{4}$.—An acid obtained, together with glycocine, by the action of potash on hyoglycocholic acid. It is insoluble in water, soluble in alcohol and ether, and crystallises in mammellated granules. Its *barium-salt* dried at 180° contains $C^{36}H^{39}Ba''O^{6}$. (Strecker.)

HYOGLYCOCHOLIC ACID. $C^{37}H^{45}NO^{6}$. Formerly called *Hycocholic acid*. (Strecker and Gundelach, Ann. Ch. Pharm. lxii. 205.)—An acid which, in the form of a sodium-salt, constitutes the principal part of the bile of the pig: hence its name (from ὗς, ὑός a pig, and χολή bile).

To prepare the sodium-salt in the pure state, the fresh bile is completely saturated with sulphate of sodium; the mixture is heated for some hours on a sand-bath, and then left to cool; and the resulting precipitate, consisting of hyoglycocholate of sodium mixed with mucus and a small quantity of yellow colouring matter, is washed with a concentrated solution of sulphate of sodium, first by decantation and then on a filter, after which it is dried at 110° C. and treated with absolute alcohol, which dissolves the hyoglycocholate of sodium. The alcoholic solution is decolorised with animal charcoal, then precipitated by ether, and the precipitate is dried at 100°.

The free acid is obtained by precipitating the aqueous solution of the sodium-salt with dilute sulphuric acid, dissolving the precipitate in alcohol and precipitating with water. The liquid is milky at first, but becomes limpid after a while, and deposits

centrated solution of carbonate of potassium, the liquid being again filtered if turbidity is thereby produced; then a large excess of the same solution; and the wh is shaken with ether as long as that liquid takes anything up. The ethereal solut separated from the watery liquid and evaporated, leaves impure hyoscyamine, wh may be purified by mixing it with water till a clear solution is produced; adding this solution twice its weight of ether-alcohol, digesting with animal charcoal, and e porating off the ether-alcohol, first at a gentle heat, and afterwards in vacuo. If residue is still coloured, it must be once more dissolved in dilute acid; the solut mixed with an equal quantity of alcohol, digested with animal charcoal, and decompo by excess of carbonate of potassium; the hyoscyamine extracted by ether; and whole process repeated if necessary.

Hyoscyamine may also be prepared, though less advantageously, from the h of the plant, while in flower, by boiling the expressed juice, filtering, mixing w lime, treating the filtrate with excess of carbonate of potassium, and dissolving out hyoscyamine by agitation with ether. The dried herb likewise yields it when trea with acidulated alcohol.

Hyoscyamine crystallises in stellate groups of silky needles, but is frequently a obtained as an amorphous sticky mass. When perfectly dry it is inodorous, but in moist state, it has an unpleasant odour resembling that of tobacco. It is soluble *water, alcohol,* and *ether*. The aqueous solution has an alkaline reaction. It me when heated, and then volatilises with partial decomposition. It is decomposed wh heated with *acids*. Strong *nitric acid* dissolves it without colour; strong *sulphu acid* turns it brown. *Iodine* added to its aqueous solution forms a copious precipit having the colour of kermes. Taken internally, even in small doses, it acts a narcotic poison. Rubbed into the eye, even in minute quantity, it produces persist dilatation of the pupil.

Hyoscyamine neutralises acids completely. Many of its salts crystallise and are p manent in the air. They have no odour, but an acrid, nauseous taste, and are v poisonous. Their solutions are not precipitated by dichloride of platinum; but yi whitish flocks with chloride of gold. With infusion of galls they form a white pre pitate.

HYPARGYRITE. See MIARGYRITE.

HYPERSPIROÏLIC ACID. Syn. with SALICYLIC ACID.

HYPER, as a prefix, syn. with PER.

HYPERSTHENE (from *ὑπέρ* and *σθένος*, strength, on account of the grea hardness and density of this mineral as compared with hornblende, with which it w formerly confounded). It is a sub-species of augite, containing, according to Mui analyses (Pogg. Ann. lxiv. 162),

SiO^2	Al^2O^3	CaO	MgO	FeO	MnO	H^2O
51·35	. .	1·83	11·09	33·92	. .	0·50 = 98·69

It is distinguished from common augite and diallage by its small proportion of calci and large proportion of iron, and may be represented by the formula $(Mg; Fe)^2SiO$

Hypersthene has a density of 3·3—3·6, and a greyish or greenish-black colour, w a more or less distinct copper-red metallic iridescence on the most distinct cleava surface, arising from the presence of microscopic laminæ of titaniferous iron imbedd in the mineral. It is remarkable that all the augitic rocks of Sweden contain titani rous iron.

The name *Paulite* is given to hypersthene found in the island of St. Paul on the coast Labrador. *Gedrite* is hypersthene in which the quantity of iron attains its maximu

HYPERSTHENITE or *Hypersthene-rock* is a crystallo-granular mixture hypersthene and labrador, with small quantities of titaniferous iron imbedded in t hypersthene, and occasional admixture of iron pyrites, mica, hornblende, olivine, garn opalite, &c. Labrador is usually the chief component. Quartz is never found in th rock. Hypersthene-rock belongs to the less frequently occurring crystalline, unstra fied formations. It is found in the island of St. Paul, on the coast of Labrador, Elfdalen in Sweden, at several localities in Norway, in the Isle of Skye, in Cornwall, the Harz in Silesia, Bohemia, &c.

The following analyses of hypersthenite are by Bunsen (Jahresb. 1861, p. 1070 *a*. Coarse-grained, containing brown hypersthene and greyish-white labradorite, fr a vein near Penig in Saxony.—*b*. Medium-grained, greenish-brown, containing greenis white labradorite and dark green augite, from Tabor, near Getschin in Bohemia.— *c*. Somewhat finer-grained and browner, from Stransko near Liebstadl.—*d*. Greyis green, crystalline, medium-grained, very slightly magnetic, containing triclinic felsp from Hrabacow near Starkenbach.—*e*. From the railway cutting of the Woleschka valle between Semil and Kostialow near Poric. It is finely crystalline, dark grey to greenis

Digitized by Google

and effervesces with acids, in consequence of small masses of calcspar disseminated through it; scarcely magnetic, and with a weathered crust:

	SiO^2	Al^2O^3	Fe^2O^3	CaO	MgO	K^2O	Na^2O	H^2O

HYPOBROMOUS ACID. BrHO.—The formation of bleaching liquids analogous to the hypochlorites by the action of bromine on solutions of the alkalis and alkaline earths was noticed by Balard in his original memoir on bromine (Ann. Ch. Phys. [2] xxxii. 337), and subsequently by Löwig (Pogg. Ann. xiv. 14, 485), Fritzsche (J. pr. Chem. xxiv. 294), and Gay-Lussac (Compt. rend. xiv. 951). Balard also found that bromine-water forms with mercuric oxide a sparingly soluble oxybromide of mercury and a bleaching liquid which, by distillation in a vacuum, yields a liquid also possessing bleaching properties, and supposed to be hypobromous acid (i. 679).

More recently, Spiller (Jahresber. 1859, 97; 1862, 73) and Dancer (Chem. Soc. J. xv. 447) have shown that when bromine is added to excess of solution of nitrate of silver, half the bromine is precipitated as bromide of silver, while the other half remains in solution as hypobromous acid, forming a strongly bleaching liquid, from which, according to Dancer, the hypobromous acid may be distilled under a pressure of 50 mm. of mercury, the liquid then boiling at 50°. The distillate, which does not contain free bromine, is straw-yellow, has an acid reaction, bleaches strongly, and decomposes when heated above 60°. It gave by analysis numbers corresponding with the formula of hypobromous acid.

Hypobromous acid is likewise obtained in solution by agitating bromine-water with excess of mercuric oxide or oxide of silver. When bromine is brought in contact with excess of dry mercuric oxide, the mixture becomes very hot. By heating the two substances together in a sealed tube to 100° a powder is obtained which smells like chloride of lime and bleaches when moistened with water; it is a mixture of mercuric oromide, oxide and hypobromite. If the bromine is in excess, a solid mass is formed consisting merely of mercuric bromide and oxide. Oxygen is set free in both cases. (Dancer.)

All attempts to prepare hypobromous anhydride by methods similar to those which yield hypochlorous anhydride (i. 908) were unsuccessful, the compound being decomposed, both at common temperatures and at −18°, into bromine and oxygen.

HYPOCHLORIC ACID. Syn. with Perchloric oxide. (See CHLORINE, OXIDES OF, i. 912.)

HYPOCHLORITE. (*Grüne Eisenerde.*)—A mineral occurring at Schneeberg, Johanngeorgenstadt, and Bräunsdorf in Saxony, in minute greenish crystals and grains, or massive and earthy. It contains, according to Schüler's analysis, 50·24 per cent. silica, 14·65 alumina, 13·03 oxide of bismuth, 10·54 protoxide of iron, and 9·62 phosphoric anhydride, with a trace of manganese, and is perhaps a silicate of bismuth and iron mixed with phosphate of aluminium. (Dana, ii. 182.)

HYPOCHLORITES. ClMO.—The formation, general properties and reactions of these salts, and the methods of estimating the quantity of available chlorine contained in them, have been already described under CHLORINE (i. 904, 908). For the preparation of hypochlorite of calcium, its uses as a bleaching and disinfecting agent, and the methods of estimating its commercial value, see *Ure's Dictionary of Arts*, &c. 904; also *Richardson and Watts's Chemical Technology*, vol. i. pt. 3, pp. 360–425.

A sample of "chloride of lime," analysed by F. Rose under the direction of Fresenius (Ann. Ch. Pharm. cxviii. 317), yielded 26·72 per cent. $CaCl^2O^2$, 25·51 $CaCl^2$, 23·05 CaO, and 24·72 combined and hygroscopic water. On repeatedly triturating it with fresh quantities of water to a thin pulp, the chloride of calcium was found to dissolve at the first trituration, the hypochlorite only at the third. Hence Fresenius concludes that the two salts exist in the bleaching powder merely in a state of mixture, or at most as a loose combination easily decomposed by water. He regards bleaching powder as a mixture of hypochlorite and basic chloride or oxychloride of calcium, $CaCl^2O^2 + (CaCl^2.2CaO) + 4H^2O$. The basic chloride is resolved by water into chloride and hydrate of calcium.

Solutions of the hypochlorites of the alkali-metals have long been used as disinfecting agents. The so-called chloride of soda or Labarraque's disinfecting liquid, is a mixture of hypochlorite and chloride of sodium, prepared by passing chlorine into a solution of caustic soda or carbonate of sodium, or by decomposing hypochlorite of calcium (bleaching powder) with carbonate or sulphate of sodium. In the first mode of preparation, about 40 lbs. of soda-crystals are dissolved in about 20

Digitized by Google

gallons of water, and a stream of chlorine is passed through the solution till it h attained a specific gravity of 1·06. A rise of the density above this point indicates t formation of chlorate of sodium. To prepare the disinfecting liquid by the secon method, about 20 lbs. of good bleaching powder are dissolved in about 26 gallons water, and to the filtered liquid is added a solution of 40 lbs. soda-crystals in abou 9 gallons of warm water. The filtered solution constitutes Labarraque's liquid.

Chloride of Potash or *Eau de Javelle* is a mixture of hypochlorite and chlorid of potassium prepared by similar methods.

A mixture of *hypochlorite of magnesium*, prepared by decomposing chloride lime with an equivalent quantity of sulphate of magnesium, is said by Claussen to more efficacious than other chlorine-compounds for bleaching flax and hemp.

Hypochlorite of Aluminium, prepared by mixing equivalent quantities of sulphate aluminium and hypochlorite of calcium, is recommended by Orioli (Rep. Pat. In April 1860) as a bleaching and antiseptic agent. It is very easily decomposed, an therefore acts very rapidly on organic matters. It may also be used as a mordan instead of acetate of aluminium, all the hypochlorous acid being disengaged at th heat of the dye-bath while the alumina remains attached to the fibre.

Hypochlorite of Zinc is also used as a mordant, and is recommended by Varrentrap (Dingl. pol. J. clviii. 378), on account of its ready decomposibility, as a bleachin agent. The action of chloride of lime may be advantageously accelerated by th addition of chloride of zinc instead of a mineral acid.

HYPOCHLOROUS ACID and **ANHYDRIDE** (i. 908).—This gas is absorbe by sulphuric anhydride, and when the latter compound, in a state of perfect drynes and in quantities of not more than 5 or 6 grms. at a time, is saturated with hypochlorou anhydride, a dark-red thickish liquid is formed, which solidifies on cooling to a mass light red needles apparently consisting of $Cl^2O.4SO^3$. These crystals melt at 55°, an detonate when suddenly raised to a higher temperature. They are instantly decom posed by water into sulphuric and hypochlorous acids; hence the compound acts a a powerful oxidising agent on sugar, alcohol, and other organic substances. Iodin decomposes it, with evolution of chlorine and formation of iodic acid.

When hypochlorous anhydride is passed into liquid sulphurous anhydride, a ver brisk reaction takes place as soon as the containing vessel is removed from the freezin mixture, chlorine being evolved and a red viscid substance remaining, composed sulphuric and hypochlorous anhydrides in a proportion not yet determined. (Schütz enberger, Compt. rend. lii. 135; liii. 538; Jahresber. 1861, p. 142.)

HYPOGÆIC ACID. $C^{16}H^{30}O^2 = \left.\begin{matrix} C^{16}H^{30}O \\ H \end{matrix}\right\}O$.—An acid belonging to the olei series $C^nH^{2n-2}O^2$, discovered in 1855 by Gössmann and Scheven (Ann. Ch. Pharm xciv. 230) in oil of earthnut (*Arachis hypogæa*) It is isomeric, if not identical, wit physetoleic acid, discovered in 1844 by Hofstädter (Ann. Ch. Pharm. xci. 177) i sperm-oil (see PHYSETOLEIC ACID), also with the acid obtained by oxidation of axini acid ($C^{18}H^{28}O^2$), an acid produced by the saponification of the fatty substance, age o axin, contained in the Mexican plant, *Coccus Axin*. (F. Hoppe, J. pr. Chem. lxxx 102.)

Preparation from Earth-nut oil.—The fatty acids of the oil are dissolved in alcohol arachidic and palmitic acids are precipitated by ammonia and acetate of magnesium the precipitate is removed; and the filtrate is mixed with ammonia and an alcoholi solution of neutral acetate of lead. The precipitate is collected after a few days, pressed and dissolved in ether; the ethereal solution is agitated with aqueous hydrochlori acid; the chloride of lead is filtered off; the filtrate is shaken up with water which ha been freed from air by boiling; the ethereal layer which separates again on leavin the liquid at rest is taken off; and the ether is removed by distillation. The remainin liquid on cooling deposits yellowish crystals, which may be purified by pressure an recrystallisation from alcohol at a very low temperature. An additional quantity o crystals may be obtained from the mother-liquor. (Gössmann and Scheven.)

Axinic acid yields by oxidation, aginin insoluble in ether, and the acid, $C^{16}H^{30}O^2$ which may be dissolved out by ether, and crystallises from the ethereal solution.

Hypogæic acid crystallises in stellate groups of needles, inodorous, melting at 34° o 35° (physetoleic acid melts at 30° and solidifies at 28°), easily soluble in alcohol an in ether.—1. When exposed to the air, it acquires a yellowish colour and rancid odour and then crystallises with difficulty, even at very low temperatures.—2. Whe subjected to dry distillation, it first gives off a reddish-yellow liquid, then yellowish white crystalline sebacic acid, and lastly, a fetid oil, leaving a small quantity of char coal.

Nitrous acid converts hypogæic acid into the isomeric compound gaïdic acid, whic is related to it in the same manner as elaïdic to oleic acid. It forms a colourless crys talline mass, permanent in the air, melting at 38°, solidifying in the radio-crystallin

Digitized by Google

form on cooling, and volatilising undecomposed at higher temperatures. (Caldwell and Gössmann, Ann. Ch. Pharm. xcix. 305.)

Hypogæic acid is monobasic. The *barium-salt* is obtained by adding alcoholic acetate of barium to an alcoholic solution of the acid mixed with excess of ammonia, in white grains which dissolve when heated and separate again on cooling.

Hypogæate of Copper, $C^{32}H^{30}Cu''O^4$, is obtained, in like manner, by mixing alcoholic cupric acetate with a hot alcoholic solution of the acid containing ammonia, and separates on cooling in violet-blue crystalline grains, soluble in alcohol and cohering to a translucent wax at 75°.—*Gaïdate of copper* is obtained by mixing aqueous gaïdate of sodium with cupric sulphate, as a scarcely crystalline precipitate, which dissolves with difficulty in alcohol, and separates therefrom in granules. It melts without decomposition at a temperature above 120°.

Hypogæate of Ethyl, $C^{16}H^{29}(C^2H^5)O^2$, is obtained by passing hydrochloric acid gas through a solution of hypogæic acid in alcohol of 95 per cent. and separates on warming the liquid, as an oil which may be freed from adhering acid by washing with small quantities of alcohol, and dried in a stream of carbonic anhydride between 100° and 120°. It is yellow, inodorous, lighter than water, but sinks in alcohol, in which it is but slightly soluble. Not volatile without decomposition.

Gaïdate of Ethyl is prepared by passing hydrochloric acid gas through a solution of gaïdic acid in absolute alcohol, precipitating after 12 hours with water, and subjecting the separated mixture of gaïdic ether and gaïdic acid to a second treatment with hydrochloric acid. The product is washed and dried at 100° in a stream of hydrogen. It is a colourless, lamino-crystalline mass, which melts between 9° and 10°, and volatilises undecomposed at a higher temperature. It is inodorous, lighter than water, heavier than alcohol, and sparingly soluble in alcohol.

Gaïdate of Silver is obtained by precipitation as a white amorphous mass which, when washed, and especially if heated with water, alcohol or ether, turns black without dissolving.

Gaïdate of Sodium is obtained by dissolving the acid in aqueous carbonate of sodium, evaporating, and exhausting the residue with absolute alcohol; the solution on cooling deposits the salt as a translucent jelly: from dilute solutions it separates in crystalline grains.

HYPOGALLIC ACID. $C^7H^6O^4$. (Matthiessen and Foster, Chem. Soc. J. xvi. 360.)—An acid produced by the action of boiling concentrated hydriodic acid on hemipinic acid (p. 142):

$$\underset{\text{Hemipinic acid.}}{C^{10}H^{10}O^6} + 2HI = \underset{\text{Hypogallic acid.}}{C^7H^6O^4} + \underset{\text{Iodide of methyl.}}{2CH^3I} + CO^2.$$

It is isomeric with carbohydroquinonic, protocatechuic and oxysalicylic acids, and intermediate in composition between salicylic acid, $C^7H^6O^3$, and gallic acid, $C^7H^6O^5$.

Hypogallic acid, when pure, is only slightly soluble in cold water, but dissolves easily in hot water, alcohol, and ether; its solution reacts strongly acid with litmus-paper. It separates from hot water in small prismatic crystals, united into stellate groups, and containing $1\frac{1}{2}$ at. water of crystallisation, which they lose at 100°. The acid melts at about 180°, but as it begins to decompose even at a lower temperature, its melting-point could not be accurately ascertained.

Hypogallic acid gradually turns brown when heated in the air to a little above 100°; the same change occurs more quickly when a solution of it, especially if neutral or alkaline, is evaporated. Added to solution of *nitrate* or *ammonio-nitrate of silver*, it causes an immediate precipitation of metallic silver, even in the cold; with *sulphate of copper* and a slight excess of potash, it gives a yellowish green solution, from which an orange-yellow precipitate is thrown down on warming; in a mixture of *sesquichloride of iron and red prussiate of potash*, it immediately produces a blue precipitate; when boiled with solution of *mercuric chloride*, it reduces it to calomel. With *sesquichloride of iron*, it gives an intense indigo-blue coloration, which is changed to violet by a very small quantity of ammonia, and to blood-red by excess of ammonia, no precipitate being produced, unless too much chloride of iron has been used; the colour is destroyed by strong acids, but restored by neutralisation with alkali, and partially by addition of water. A solution of the acid immediately becomes brown on addition of *alkali*, the colour quickly becoming darker by exposure to the air. With *ammonia and chloride of barium* or *calcium*, it gives a brownish white flocculent precipitate; with *acetate of lead*, a pale yellow precipitate.

Hypogallic acid is decomposed by heat into carbonic anhydride and a substance which solidifies in the neck of the retort to a colourless crystalline mass. The decomposition begins at about 170°, and goes on rapidly at 200°. The crystalline product melts, in the crude state, at about 90°; it dissolves easily in water, and crystallises in needles when the solution is evaporated. It is rapidly attacked by nitric

Digitized by Google

acid, even when diluted, giving a red-brown solution. With sesquichloride of i gives a bluish-black amorphous precipitate; with acetate of lead it gives a wh yellowish-white precipitate, soluble in an excess of acetic acid. It slowly assu darker colour by exposure to air in contact with alkali. This substance has n been prepared in sufficient quantity for complete investigation.

The three acids above mentioned as isomeric with hypogallic acid, have abou same solubility in water, alcohol, and ether, as the latter; they all likewise give a coloration with the smallest trace of sesquichloride of iron; reduce nitrate of si become dark brown when mixed with alkali and exposed to the air; give a yello white precipitate with acetate of lead; and at a high temperature are all decom into carbonic anhydride and oxyphenic acid or hydroquinone. Nevertheless, n of these acids appear to have quite the same properties. The following are the important points in which differences have been observed. Hypogallic acid crysta with $1\frac{1}{2}$ molecule of water (14·9 per cent.), carbohydroquinonic and protocatechuic with 1 molecule (10·4 per cent.), and oxysalicylic acid without water. Hypogalli oxysalicylic acids give a dark-blue colour with sesquichloride of iron, the othe acids a dark-green colour. Hypogallic acid reduces nitrate of silver immediat the cold; carbohydroquinonic acid reduces it slowly in the cold, rapidly when b oxysalicylic acid has no action on nitrate of silver in the cold, but reduces it comp when boiled. Carbohydroquinonic acid reduces cuprous oxide from a mixture of acetate, tartaric acid, and excess of potash; protocatechuic acid causes no reducti the same solution. Hypogallic acid causes a precipitate in a mixture of chlori barium and ammonia; protocatechuic acid only on addition of alcohol. Some of differences may perhaps be due to accidental causes, depending on the different so and modes of preparation.

HYPO-IODIC ACID. See IODINE, OXACIDS OF.

HYPONIOBIC ACID. See NIOBIUM.

HYPONITRIC ACID. Syn. with Pernitric oxide. (See NITROGEN, OXIDE

HYPONITROMECONIC ACID. Syn. with Nitromeconin. (See MECO

HYPONITROUS ACID. Syn. with NITROUS ACID.

HYPOPHOSPHOROUS ACID. See PHOSPHORUS, OXYGEN-ACIDS OF.

HYPOSCLERITE. A name applied by Breithaupt to a mineral from Ar which, according to Rammelsberg, is probably albite mixed with augite. (See A under FELSPAR.)

HYPOSTILBITE. Syn. with STILBITE.

HYPOSULPHAMYLIC ACID. Syn. with Amyl-sulphurous acid. (See PHUROUS ETHERS.)

HYPOSULPHARSENIOUS ACID. Syn. with Disulphide of Arsenic. ARSENIC, SULPHIDES OF, i. 386.)

HYPOSULPHETHYLIC ACID. Syn. with Ethyl-sulphurous acid. SULPHUROUS ETHERS.)

HYPOSULPHINDIGOTIC ACID. } See INDIGO-SULPHURIC ACIDS.
HYPOSULPHOCERULIC ACID. }

HYPOSULPHOGLUTIC ACID. Syn. with SULPHOGLUTIC ACID.

HYPOSULPHOMETHYLIC ACID. Syn. with Methyl-sulphurous acid. SULPHUROUS ETHERS.)

HYPOVANADIC ACID. See VANADIUM.

HYPOXANTHINE. An azotised organic substance discovered by Sch (Ann. Ch. Pharm. lxxiii. 328) in the spleen of man and in the ox, and since fou exist in many other parts of the animal body. It is probably identical with SA (*q.v.*)

HYSSOPINE. A doubtful alkaloïd, said by Herberger to exist in the he *Hyssopus officinalis*.

HYSSOP, OIL OF. A volatile oil obtained from *Hyssopus officinali*

Digitized by Google

distillation with water. It is yellow when fresh, but turns red by keeping; has a sharp taste and smells like camphor.

HYSTATITE. Syn. with ILMENITE.

I

IASPACHATES. A variety of agate.

IDERITE. A silicate from Montoval, near Toledo, occurring in large six-sided prisms with basal cleavage. Hardness = 2·5. Specific gravity = 2·89. Contains, according to Norlin (Kongl. Vetensk. Akad. Förhandlingar, 1844, 215), 40·90 per cent. SiO^2, 30·74 Al^2O^3, 15·47 FeO, MnO 1·33, 0·40 CaO, 0·81 MgO, 4·57 K^2O, 0·04 Na^2O, 5·56 H^2O = 99·82. Fuses to a dark pearl before the blowpipe. It is probably allied to dichroïte.

ICE-SPAR. A name sometimes applied to a transparent variety of felspar found in Vesuvian lavas: the term includes pellucid varieties of other species of felspar. (Dana.)

ICELAND-SPAR. Transparent calc-spar. (See CALC-SPAR.)

ICHTHIDIN. A substance contained in the immature eggs of cyprinoïd fishes.

ICHTHIN. The azotised constituent of the eggs of cartilaginous fishes. It is easily extracted from the eggs of the ray by pouring the yolk into a large quantity of distilled water, washing the dense granules which fall to the bottom till the wash-water contains only traces of albumin and saline matters, and finally exhausting them with alcohol and ether.

Ichthin thus obtained forms homogeneous, white, transparent grains, soft to the touch, insoluble in water, alcohol, and ether. Hydrochloric acid dissolves it without violet coloration; it is also readily soluble in dilute acetic and phosphoric acid, and in other acids in the concentrated state. Solutions of potash and soda dissolve it slowly; ammonia does not act upon it. It gives by analysis 50·2 to 51·0 per cent. carbon, 6·7 to 7·8 hydrogen, 14·7 to 15·4 nitrogen, and 1·9 phosphorus (?). It does not appear to contain sulphur. It leaves but a trace of ash when burnt. (Valenciennes and Frémy, Compt. rend. xxxviii. 480, 528.)

ICHTHULIN. The very young eggs of cyprinoïd fishes contain, besides icthidin, a strongly albuminous liquid which holds in suspension certain mineral salts, together with ichthulin, which may be precipitated by water. When first precipitated, it is viscid like gluten; but when treated with alcohol and ether, it loses its viscosity and becomes solid and pulverulent. Like ichthin, it dissolves in acetic and in phosphoric acid, also in hydrochloric acid, without violet coloration. It contains 52·5 to 53·3 per cent. carbon, 8·0 to 8·3 hydrogen, 15·2 nitrogen, 1·0 sulphur, and 0·6 phosphorus (?). It seems to disappear as the eggs approach maturity, and to be replaced by albumin. (Valenciennes and Frémy.)

ICHTHYOCOLL or **ISINGLASS.** See GELATIN (ii. 826).

ICHTHYOPHTHALMITE. Syn. with APOPHYLLITE (i. 351).

ICICA-RESIN. A resin very similar to elemi, obtained from trees very common in Guiana, belonging to the order *Terebinthaceæ*. It occurs in small masses or opaque grains, having a yellowish-white colour, and a sweet, rather agreeable odour, the strength of which is increased by heat. It is friable and tasteless. It gives up nothing to water, and is but sparingly soluble in alcohol, requiring for complete solution 45 parts of cold alcohol of 36°, and 15 parts of boiling alcohol; it dissolves also in 3½ parts of oil of turpentine at ordinary temperatures. It is insoluble in alkalis. Its alcoholic solution does not precipitate lead or silver salts.

Icica-resin is composed of three distinct substances, separable by their different degrees of solubility in alcohol.

a. If the resin be completely dissolved in boiling alcohol, one of these substances, viz. brean, crystallises on cooling. It has the composition of cholesterin, and forms white, tasteless, needle-shaped crystals, insoluble in water and in alkalis, sparingly soluble in alcohol, and having a neutral reaction. It melts at 137°, and solidifies on cooling to a mass resembling amber. By dry distillation it yields empyreumatic oils, a volatile, solid, amorphous substance which collects in the neck of the retort, and a small residue of charcoal. It is dissolved, with red colour, by sulphuric acid, and precipitated unaltered by water. Nitric acid decomposes it, with evolution of nitrous fumes, forming a yellow body soluble in excess of nitric acid, and precipitated on addition of water.

Digitized by Google

b. On removing the brean and concentrating the mother-liquor, a certain quantity of the same substance, in an impure state, first separates, and afterwards another crystalline resin, icican, which has the same melting-point as brean, and resembles it in most of its other properties, but is distinguished by its greater solubility in alcohol. It gives by analysis 82·01 per cent. C, 11·65 H, and 6·34 O, which may be represented by the formula $C^{20}H^{34}O$. Its composition is about the same as that of the resin of *Ceroxylon Andicola*.

c. The mother-liquor of icican, after being completely freed from crystallisable matter, deposits a small quantity of a yellow amorphous resin, which melts below 100°, and is much more soluble in alcohol and ether than brean or icican. Its alcoholic solution is slightly acid to test-paper, but the resin does not dissolve in alkalis. It contains 77·93 per cent. C, 10·69 H, and 11·47 O, corresponding approximately with the formula $C^{20}H^{30}O^2$. (Scribe, Ann. Ch. Phys. [3] xiii. 166.)

IDIOTYPE. A term applied by Guthrie (Chem. Soc. J. xiii. 35) to bodies derived by replacement from the same substance, including the typical substance itself; ammonia, for example, is idiotypic with ethylamine, phenylamine, and all the organic basis derived from it by substitution, and these are idiotypic one with the other.

The same term was applied by Wackenroder (J. pr. Chem. xxiv. 18) to certain non-crystalline organic bodies which, according to his observations, exhibit certain similarities of structure.

IDOCRASE. See Vesuvian.

IDRIALIN. $C^{42}H^{28}O$ (?).—The essential constituent of idrialite, from which it is obtained either by dry distillation in an atmosphere of carbonic anhydride—or better, by boiling the mineral with rock-oil or oil of turpentine; the liquid on cooling solidifies in a mass, which may be freed from the solvent by means of bibulous paper.

Idrialin forms colourless scales, which melt at a very high temperature, with partial decomposition. When distilled, it partly volatilises, but at least $\frac{9}{10}$ of it is decomposed at the same time, even in an atmosphere of carbonic anhydride. It is insoluble in *water*, even at the boiling heat, and nearly insoluble in *alcohol* and *ether;* the best solvent for it is boiling *oil of turpentine*. It gives by analysis 91·7 to 92·0 per cent. carbon, and 5·1 to 5·4 hydrogen, agreeing nearly with the formula above given—which requires 91·07 C, 5·11 H, and 2·92 O. (Bödeker, Ann. Ch. Pharm. lii. 100.) Dumas and Laurent regarded it as a hydrocarbon $C^{15}H^{10}$, but these results were calculated according to the old atomic weight of carbon.

Idrialin heated with strong *sulphuric acid* forms a solution of a fine blue colour, like that of sulphindigotic acid. The solution diluted with water forms with bases peculiar salts, among which the potassium-salt is distinguished by its beautiful crystalline character.—Idrialin boiled with strong *nitric acid* yields a red powder (Laurent's *nitrite of idrialase*) destitute of taste and odour, insoluble in water and ether, soluble in sulphuric acid, to which it imparts a mahogany colour. In potash it dissolves with brown colour. Heated in a closed tube, it decomposes with explosion and emission of light. According to Laurent's analysis, it contains 62·7 to 63·3 per cent. carbon, 3·2 to 3·0 hydrogen, and 10·5 nitrogen, approximating to the formula $C^{42}H^{23}(NO^2)^3O$. (65·2 C, 2·9 H, and 9·0 N).

IDRIALITE. The mineral from which idrialin is obtained. It is found in the quicksilver mine of Idria, mixed with cinnabar, and is sometimes called *inflammable cinnabar* (*Quecksilberbranderz*). It is massive and opaque, with greasy lustre, greyish or brownish-black colour, and blackish streak inclining to red. Specific gravity, 1·4 to 1·6. Hardness, 1 to 1·5.

IDRYL. Bödeker found in a product obtained by the dry distillation of the quicksilver ore of Idria in a close vessel, two peculiar hydrocarbons, one of which (*idryl*) formed mammellated groups, fusible at 86°, volatile without decomposition, very soluble in alcohol, ether, acetic acid, and oil of turpentine; while the other formed scales melting above 100°, volatilising before melting, and much more soluble than the former. Their composition agreed nearly with the formula, nC^3H^2 (94·7 C and 5·3 H).

IGASURIC ACID. Pelletier and Caventou (Ann. Ch. Phys. [2], x. 142). An acid contained, in very small quantity, combined with strychnine, in the bean of St. Ignatius; also in *nux vomica*, and in the root of *Strychnos colubrina*. It is prepared by washing the magnesia which has served for the preparation of strychnine, with cold water, till the colouring matter is removed, then boiling it with a large quantity of distilled water, which dissolves the igasurate of magnesium, precipitating it with acetate of lead, decomposing with sulphydric acid, and evaporating to a syrup. The acid is then deposited, after a while, in small hard granular crystals. It has a sour, styptic taste, and is very soluble in water and in alcohol. Corriol regards it as identical with lactic acid; but, according to Marsson (Ann. Ch. Pharm. lxxii. 296), this identity does not exist, for igasuric acid precipitates acetate of lead, which lactic acid does not.

Digitized by Google

The *igasurates* are for the most part soluble in water and in alcohol. The *ammonium-salt* is perfectly neutral, does not precipitate the salts of iron, mercury, or silver, but colours copper-salts green, and then forms a greenish-white precipitate sparingly soluble in water.

IGASURINE. An alkaloïd, discovered in 1853 by Desnoix (J. Pharm. [3], xxv. 202). It exists in *nux vomica*, and is found in the mother-liquors from which strychnine and brucine have been precipitated by lime at the boiling heat. These mother-liquors, if sufficiently concentrated, deposit the igasurine in crystals on the sides of the vessel. It may be purified by dissolving in water acidulated with hydrochloric acid, treating the solution with animal charcoal, precipitating by ammonia, and recrystallising.

Igasurine crystallises in colourless prisms, having a silky lustre. It is more soluble in *water* than strychnine or brucine, dissolving in 200 parts of cold and 100 parts of boiling water; it is sparingly soluble in *ether*, very soluble in *alcohol*. The alcoholic solution turns the plane of polarisation to the left: $[\alpha] = -62{\cdot}9°$. It has not been analysed, but its atomic weight appears to be intermediate between those of strychnine and brucine.

Igasurine, when heated, melts and gives off water (about 10 per cent.); at a higher temperature, it is decomposed, with evolution of ammoniacal vapours. Strong *sulphuric acid* communicates to it a rose-colour, which passes to yellow, and then to yellowish-green. *Nitric acid* colours it deep red like brucine; on adding a few drops of stannous chloride, the colour changes to violet. *Chlorine*, passed into a very dilute solution of hydrochlorate of igasurine, produces first a rose, then a red, then a yellow colour, each bubble of gas being enveloped by a white pellicle, which is gradually deposited in the pulverulent form. If the stream of chlorine be discontinued, the precipitate redissolves on agitation, and the solution soon afterwards loses its red colour, retaining only a slight greenish tint. *Iodide of potassium*, added to a solution of igasurine, produces a crystalline precipitate after a considerable time; *ioduretted iodide of potassium* immediately forms a brown precipitate. Igasurine is not precipitated by chlorate of potassium, but its solutions yield a yellow precipitate with *tetrachloride of platinum*, white with *tannin*, and with *infusion of galls*.

Igasurine is intensely poisonous, being intermediate in power between strychnine and brucine.

Igasurine dissolves easily in dilute *acids*, and is precipitated from the solutions by *potash, soda, and ammonia*, the precipitate redissolving in excess of the alkali, especially in potash. It is also precipitated in needle-shaped crystals by *acid carbonate of sodium*, or *potassium*, in presence of tartaric acid.

The salts of igasurine are for the most part crystallisable. The *sulphate* forms colourless, silky crystals, soluble in about 4 pts. of boiling water, and 10 pts. of cold water. The *hydrochlorate* resembles the sulphate in form, but dissolves in 2 pts. of hot, and about 4 pts. of cold water. The *nitrate* forms colourless crystals, more soluble in water than either of the preceding salts.

According to Schützenberger (Compt. rend. xlvi. 1234; Ann. Ch. Pharm. cviii. 348), igasurine, prepared as above from the seeds of *Strychnos nux vomica*, yields by treatment with hot water, and fractional crystallisation, no fewer than nine distinct bases, all colourless, very bitter, and acting like strychnine. They crystallise in transparent needles, or in nacreous bulky geodes. They are reddened by nitric acid like brucine, which they also resemble in their chemical reactions, but they are more soluble in water and in alcohol. They all contain water of crystallisation (3 or 4 at.), which they give off at 100°. Schützenberger distinguishes them as *a*, *b*, *c*, &c. igasurine, and assigns to them the following formulæ:

Igasurine	*a*.	$C^{36}H^{16}N^2O^3.3H^2O$ very slightly soluble.
,,	*b*.	$C^{16}H^{24}N^2O^7.3H^2O$ slightly soluble.
,,	*c*.	$C^{16}H^{24}N^2O^4.3H^2O$ moderately soluble.
,,	*d*.	$C^{17}H^{22}N^2O^8.3H^2O$,,
,,	*e*.	$C^{16}H^{26}N^2O^4.3H^2O$,,
,,	*f*.	$C^{21}H^{30}N^2O^4.3$ or $4H^2O$,,
,,	*g*.	$C^{21}H^{28}N^2O^6.3H^2O$ very slightly soluble.
,,	*h*.	$C^{21}H^{28}N^2O^6.3H^2O$ moderately soluble.
,,	*i*.	$C^{36}H^{30}N^2O^7.3H^2O$,,

Igasurine *f* yields, by oxidation with nitrous acid, a base having the formula $C^{21}H^{28}N^2O^6$, which crystallises in colourless needles, containing 4 at. water, melting in their water of crystallisation at 100°, and coloured red by nitric acid.

In the absence of confirmatory evidences, these results must be considered rather doubtful.

IGLESIASITE. Syn. with Horn-Lead. (See Lead, Chloride of.)

Digitized by Google

IGLITE or **IGLOÏTE.** Syn. with ARRAGONITE (i. 358).

ILDEFONSITE. A columbite from Ildefonso, in Spain, having a subme vitreo-adamantine lustre. Specific gravity 7·416 (Dana, ii. 355).

ILICIC ACID. (Moldenhauer, Ann. Ch. Pharm. cii. 350).—An acid tained in the leaves of the holly (*Ilex aquifolium*). It is known only in combin with bases. To prepare the calcium-salt, an aqueous decoction of the leaves is cipitated with basic acetate of lead; the filtrate, freed from lead by sulphydric is heated with hydrate of lead; the dissolved lead is again removed by sulph acid; and the filtrate is reduced to a syrup. The laminæ formed after some day purified by pressing, dissolving in water, precipitating with alcohol, and recrystall with the help of animal charcoal, whereby colourless ilicate of calcium is obtaine

Ilicate of calcium contains 12·86 per cent. calcium, and is readily soluble in wate insoluble in alcohol. An aqueous solution does not precipitate salts of *manganese*, *iron*, *copper*, or *silver*, but produces a precipitate with *stannous chloride*, and wit *neutral* and *basic acetates of lead*. When the lead-salts are decomposed by sulph acid, a colourless syrup is formed, which still contains lime, and by neutralisation carbonate of barium, yields amorphous ilicate of barium.

Holly-leaves gathered in January contain gum, or a similar substance, which i feres with the extraction of the acid.

ILICIN. The bitter principle of *Ilex aquifolium*. According to Délescha (Repert. Pharm. xli. 230), the decoction of the leaves is precipitated with basic ac of lead; carbonate of potassium is added to make the liquid filter, and to preci any excess of the lead-salt; and the filtrate is acidified with dilute sulphuric acid, filtered, saturated with carbonate of calcium, and evaporated to a syrup. Al extracts from the syrup a light brown, very hygroscopic substance, which, in layers, dries up to small shining scales. Or, the aqueous extract is exhausted alcohol, the alcoholic solution evaporated, and the dry residue exhausted water at 40°. The filtrate is precipitated with basic acetate of lead, freed from e of lead by sulphydric acid, evaporated, and treated with alcohol, which takes u ilicin, and leaves it behind on evaporation. The aqueous solution of the alc extract may also be treated, as above, with acetate of lead, dilute sulphuric acid carbonate of calcium in succession, the filtrate evaporated, and the ilicin extr from the residue by alcohol. It is a bitter, amorphous, brown, very hygroscopic (still containing a little potash), converted by acids at a gentle heat into a black stance, with empyreumatic odour. It is soluble in water and alcohol, insolub ether.—Lebourdin (Ann. Ch. Pharm. lxvii. 254) agitates the decoction of the l with animal charcoal, then heats it therewith to boiling; leaves it to cool; re the now colourless and tasteless liquid; washes the charcoal with cold water; it with alcohol; and leaves the filtrate to evaporate: it then leaves a colourless, bitter syrup, and finally an amorphous, neutral jelly, easily soluble in water a alcohol.—Moldenhauer's ilicin (Ann. Ch. Pharm. cii. 352) appears also to be diff from this. Moldenhauer removes the alcohol from the alcoholic extract of the l by distillation, and the separated resin by filtration; precipitates with basic acet lead; washes the yellow precipitate, and decomposes it under water with hydrosulp acid. The sulphide of lead, after being well boiled with water, yields the ilic alcohol, as a very bitter, dark brown substance, resembling tannin, and sligh water.—Bennemann (N. Br. Arch. xciii. 4) gives the name of ilicin to crystals he obtains as follows: He precipitates the decoction with basic acetate of decomposes the washed precipitate under water with sulphydric acid; filters the from the sulphide of lead, and evaporates to dryness. By repeatedly exhaustin residue with alcohol, and leaving the solution to evaporate, needles were f obtained, but not in sufficient quantity for further examination.

ILIXANTHIN. $C^{17}H^{32}O^{11}$. (Moldenhauer, Ann. Ch. Pharm. cii. 346. substance occurring in the leaves of the holly (*Ilex aquifolium*). The leaves gat in January contain scarcely any ilixanthin, while those gathered in August con large quantity. The leaves are exhausted with alcohol of 80 per cent.; the tin thus obtained is freed from the greater part of the alcohol by distillation; an residue is set aside to crystallise. The granules, which separate after some day dried, washed with ether to remove the green colouring matter of the leaves, diss in alcohol, and again separated by evaporation and addition of water; they are, recrystallised from hot water. A further quantity of ilixanthin may be obtained the mother-liquor by reducing it to a syrup, dissolving in absolute alcohol, evapo the alcoholic solution, dissolving the residue in water, and precipitating with acetate of lead. The washed precipitate is decomposed under hot water with sulph acid, and the filtrate is evaporated to a syrup, whereupon the ilixanthin crystallis in straw-yellow microscopic needles, which melt at 198° to transparent red-yellow

Digitized by Google

Ilixanthin boils and decomposes at 215°. It does not reduce an alkaline solution of *cupric oxide*, even on prolonged boiling. It is nearly insoluble in cold *water*, but dissolves easily in hot water, forming a yellow solution; also in *alcohol*, but is insoluble in *ether*. It dissolves in warm concentrated *hydrochloric acid*. The colour of the aqueous solution is changed to orange-yellow by *alkalis* and *alkaline carbonates*, but becomes colourless on addition of sulphuric acid. *Ferrous* and *cupric salts* do not affect ilixanthin; *ferric chloride* colours it green. Neutral or basic *acetate of lead* produces in the aqueous solution of ilixanthin a splendid yellow precipitate, soluble without colour in acetic acid.

Ilixanthin forms a yellow dye on cloth prepared with alumina or iron mordants.

ILMENITE. Titaniferous Iron. See TITANATES.

ILMENIUM. According to Hermann (J. pr. Chem. xxxviii. 91, 119; xl. 475; lxv. 52), Siberian yttrotantalite, or yttroilmenite, contains a peculiar metal which forms an acid, ilmenic acid, closely resembling niobic acid (see NIOBIUM), but, nevertheless, distinguished from it by its lower specific gravity, by the insolubility of its hydrate in hydrochloric acid, and by forming with sulphuric acid a compound which is decomposed by a large quantity of water, leaving a residue of hydrated ilmenic acid. According to H. Rose, however (Pogg. Ann. lxxi. 167), the supposed ilmenic acid is merely niobic acid, more or less impure. Rose also regards yttro-ilmenite as identical with uranotantalite or Samarskite (*q. v.*)

ILVAITE. See LIEVRITE.

IMABENZILE. $C^{14}H^{11}NO$. (Laurent, Rev. scient. x. 122; J. pr. Chem. xxvii. 312.)—Produced, together with benzilam and benzilimide, by the action of ammonia on benzile:

$$C^{14}H^{10}O^2 + NH^3 = C^{14}H^{11}NO + H^2O.$$

Benzile is dissolved in warm absolute alcohol; dry ammoniacal gas is passed through the still warm solution; and the liquid is left to cool, while the passage of the gas is continued. After 24 hours, the liquid, together with the sediment which has formed, is heated to the boiling point, and filtered at the same temperature. Imabenzile then remains on the filter, and may be purified by washing with ether.

Imabenzile is a white inodorous powder, which separates from its solution in boiling ether-alcohol, in microscopic right rhombic prisms with dihedral summits, whose faces rest on the obtuse lateral edges. It melts at 140°, remains soft and glutinous on cooling, and then solidifies without crystallising. It is quite insoluble in boiling alcohol and ether. It is partially decomposed during fusion. When subjected to dry distillation, it neither gives off gas nor leaves any carbonaceous residue. When gently heated with *nitric acid*, it gives off red vapours, and yields a yellow oil, which solidifies in the crystalline form on cooling, dissolves in alcohol, and crystallises therefrom in small needles united in tufts, but is insoluble in ammonia. It is not altered by boiling with hydrochloric acid. It dissolves in gently heated *sulphuric acid*, and the solution, mixed with water, deposits benzilam. It dissolves readily in boiling alcoholic potash; and water added to the solution throws down benzilimide, while nothing but potash remains dissolved.

IMASATIC ACID. Syn. with ISAMIC ACID.

IMASATIN. $C^{16}H^{17}N^3O^3$. (Laurent, Ann. Ch. Phys. [3] iii. 483.)—A compound produced by boiling a solution of isatin in ammonia. It is of a greyish-yellow colour, often inclining to brown or green, and crystallises sometimes in lamellated grains, sometimes in radiated spheres of a darker colour. It is insoluble in water and in ether, very sparingly soluble in boiling alcohol. It is decomposed by dry distillation, yielding a large quantity of charcoal and a sublimate of colourless needles. It is not attacked by boiling hydrochloric acid. Caustic potash dissolves it, and the solution, diluted with water and neutralised by an acid, yields a whitish, gelatinous precipitate.

Dichlorimasatin, $C^{16}H^9Cl^2N^3O^3$, is a powder of slightly reddish colour, produced by the action of ammonia on an alcoholic solution of chlorisatin.

Tetrabromimasatin, $C^{16}H^7Br^4N^3O^3$. Reddish-yellow scales produced by the action of ammonia on tetrabromisatin.

IMATRA STONES. Stony concretions found in a marly formation on the Schuttgebirg in Finland. They were regarded by Parrot (Petersb. Acad. Bull. 1839, vi. 183) as petrified molluscs, on the ground that they contained calcium and sulphur, neither of which elements were found by him in the formation in which they were imbedded. On the other hand, Virlet (Bull. Géol. ii. 219; iv. 22; Jahresber. 1847-8, p. 1298) regarded them merely as calcareo-aluminous concretions produced by molecular attraction. The concretions (*A*), and the formation (*B*) in which they are found,

Digitized by Google

have been analysed by Ulex (Jahresber. 1861, p. 1086); the latter, also (B') Salvétat (*ibid.* 1298):

	SiO^2	$CaCO^3$	Al^2O^3	Fe^2O^3	Mn^3O^4	H^2O	Alkali	TiO^2 and MgO	
A.	70·3	. .	15·1	8·8	2·1	3·7	. .	. .	= 100·0
B.	31·8	51·1	8·2	6·5	2·4	. .	. .	. .	= 100·0
B'.	34·1	47·8	9·0	4·0	2·0	. .	0·5	traces	= 97·4

IMESATIN. $C^8H^6N^2O$. (Laurent, *loc. cit.*)—Obtained by passing dry monia gas into a boiling solution of isatin in absolute alcohol, in which a slight exce pulverised isatin is suspended. It forms colourless right prisms, with rectangular l inodorous, insoluble in water, moderately soluble in boiling alcohol, very sparing ether. Heated with a small quantity of alcohol and hydrochloric acid, it diss readily and decomposes, yielding isatin and sal-ammoniac. The same decompos is produced by potash.

Chlorimesatin, $C^8H^5ClN^2O$, resembles imesatin, and is obtained in like manner chlorisatin. It forms yellow hexagonal scales, sparingly soluble in boiling alc nearly insoluble in ether. It is slowly decomposed by boiling water, with evoluti ammonia. When heated, it gives off ammonia, yields a sublimate of yellow nee and leaves charcoal.

IMIDES. Monamides, in which 2 at. hydrogen are replaced by a diatomic rad *e.g. succinimide*, $N(CO)''H$; *pyro-tartrimide*, $N(C^3H^6O)''H$. (See Amides.)

IMPERATORIA OSTRUTHIUM. (*Masterwort.*)—The root of this (analysed by Keller) contains 0·2 per cent. of a resin called imperatorin or peucedi 16·0 fat and volatile oil; 5·6 extract soluble in water and alcohol; 8·8 gum and soluble in water; 9·2 starch and extract soluble in boiling water; 41·2 vegetable and 19·0 water (and loss). (Pelouze and Frémy, *Traité*, vi. 398.)

IMPERATORIN. See Peucedanin.

INCINERATION. See Ash (i. 417).

INDELIBROMIL. $C^{16}H^8Br^4N^2O^4$.—A yellow substance, insoluble in w produced by the action of bromine on isamic acid. (Laurent.)

INDIANITE. A variety of anorthite (i. 308) found in the Carnatic, diff somewhat from ordinary anorthite (from Vesuvius) in the composition of the proto which it contains. According to Laugier's analysis (Mem. du Mus. d. hist. na 341), it contains 42·0 to 43·0 per cent. SiO^2, 34·0—34·5 Al^2O^3, 15·0—15·6 CaO, 3 2·6 Na^2O, 3·20—1·0 Fe^2O^3, and 1·0 water.

INDIAN INK or **CHINA INK.** A black pigment, the best varieties of w are imported from China. It is composed of a very fine black, said by Prechot obtained from camphor, cemented together with gelatin.

INDIAN RED. A mineral from the Persian Gulf, used as a pigment. The coarse powder has a dark red colour, with a tinge of purple. Specific gravity 3 The following analyses, A, of the entire mineral, B, of the portion soluble in h chloric acid, are by How (Edinb. New Phil. J. new series, ii. 306; Jahresber. p. 925):

	SiO^2	Fe^2O^3	Al^2O^3	CaO	MgO	SO^3	CO^2	H^2O	
A.	30·17	56·59	3·79	2·65	1·43	2·28	1·73	1·62	= 100·26
B.	(. .	3·91	2·22	2·65	0·87	2·28	1·73	. .)	= 13·66

The principal portion (insoluble in hydrochloric acid) is a ferric silicate, $Fe^2O^3.3$ The name Indian red is also applied to another pigment of similar colour, co ing chiefly of sesquioxide of iron.

INDIAN YELLOW or **PURREE.** A yellow pigment consisting essentia euxanthate of magnesium. (See Euxanthic Acid, ii. 609, and Purree.)

INDICAN. $C^{26}H^{31}NO^{17}$ (Schunck, Phil. Mag. [4] x. 73; xv. 29, 117, Jahresber. 1855, p. 660; 1858, p. 465.—Gm. xvi. 1.)—A colourless substance exi in woad, and most probably in other plants which yield indigo-blue. It likewise c in human urine, both healthy and diseased, and when present in considerable qua causes the urine, after spontaneous fermentation, or on addition of acids, to de sometimes indigo-blue, sometimes indirubin. It may be detected by precipitatin urine with basic acetate of lead, collecting the precipitate which forms in the fi on addition of ammonia, and decomposing it with cold dilute acids, the filtrate depositing, first, indigo-blue, then indirubin, and afterwards other products o decomposition of indican. Indican is also found in the blood of man, and in the and urine of the ox. (Carter, Ed. Med. J., Aug. 1859.)

Preparation.—From woad-leaves, carefully dried and pulverised while warm.—1. leaves are exhausted with cold alcohol in a percolating apparatus; the green tin

Digitized by Google

is precipitated with alcoholic sugar-of-lead and a little ammonia-water; and the pale green precipitate, after washing with cold alcohol, is decomposed under water by a stream of carbonic anhydride; it then loses its colour, and yields a yellow solution, which, when freed from dissolved lead by sulphydric acid, and evaporated over oil of vitriol, yields indican.—2. The tincture prepared with cold alcohol is concentrated, after addition of a little water, by passing a stream of air over it at the common temperature; the fat which separates is removed by filtration; the filtrate shaken up with recently precipitated cupric hydrate; the liquid again filtered; the filtrate freed from dissolved copper by sulphydric acid; and the liquid separated from the sulphide of copper is evaporated at the temperature of the air. From the residual brown syrup, cold alcohol dissolves out the indican, leaving undissolved a brown viscid mass which contains oxindicanin. By mixing the alcoholic solution with 2 vol. ether, further products of decomposition are precipitated, whilst the indican is obtained by evaporating the filtrate. When thus prepared it still retains a little fat.

Properties.—Indican forms a yellow or yellow-brown syrup, which cannot be dried without decomposing. It has a slightly bitter and repulsive taste, dissolves in *water*, with yellow colour, also in *alcohol* and *ether*. The alcoholic solution forms, with acetate of lead, a sulphur-yellow precipitate, which increases on addition of ammonia; the aqueous solution is precipitated by acetate of lead only after addition of ammonia.

Decompositions.—1. Indican decomposes even when gently warmed, and at a stronger heat swells up and emits vapours which condense to an oil, solidifying partially in the crystalline form.

2. The aqueous solution is decomposed by heat, and by spontaneous evaporation, yielding the following products:

a. Oxindicanin, $C^{26}H^{22}NO^{16}$. This compound separates on spontaneous evaporation, and may be purified by repeated solution in water and precipitation by alcohol. It is a brown viscid combustible gum, having a nauseous taste; by boiling with dilute sulphuric acid, it is resolved into indifuscin and indiglucin:

$$\underset{\text{Oxindicanin.}}{2C^{26}H^{22}NO^{16}} = \underset{\text{Indifuscin.}}{C^{24}H^{20}N^2O^9} + \underset{\text{Indiglucin.}}{2C^6H^{10}O^5} + 4CO^2 + 3H^2O$$

b. Oxindicasin.—Produced when an aqueous solution of indican is evaporated by heat, the indican, according to Schunck, being first converted, with separation of indiglucin, into indicanin, the latter, with absorption of oxygen, into oxindicanin, and this last being resolved, with assumption of water, into oxindicasin and indiglucin:

$$\underset{\text{Oxindicanin.}}{2C^{26}H^{22}NO^{16}} + 3H^2O = \underset{\text{Oxindicasin.}}{C^{24}H^{22}N\,O^{13}} + \underset{\text{Indiglucin.}}{2C^6H^{10}O^5}$$

It is purified like the preceding, which it resembles. Its aqueous solution, precipitated with excess of neutral acetate of lead, yields a yellow lead-salt containing $C^{24}H^{22}N^2.4Pb^2O$.

c. Indicasin.—The liquid filtered from the lead-salt of oxindicasin, and containing excess of lead-acetate, yields, when treated with a large quantity of alcohol, a pale yellow precipitate = $C^{24}H^{16}N^2O^{22}.6Pb^2O$.

3. In contact with *soda-ley* or *baryta-water*, indican is resolved into indicanin and indiglucin:

$$\underset{\text{Indican.}}{C^{26}H^{31}NO^{17}} + H^2O = \underset{\text{Indicanin.}}{C^{26}H^{29}NO^{16}} + \underset{\text{Indiglucin.}}{C^6H^{10}O^5}$$

A solution of indican, left for several days in contact with soda-ley, yields, with acids, indirubin produced from the indicanin; after longer standing, indiretin is likewise obtained, and in some cases the latter is the only product.

4. Indican is decomposed by dilute *acids* in the cold, and more quickly when heated. The decomposition is induced by tartaric and oxalic acids, as well as by mineral acids, less easily by acetic acid. Aqueous indican mixed with dilute sulphuric acid, becomes turbid on standing, and deposits blue flocks, the formation of which ceases after 24 hours. The filtrate, after standing for some time, and still more when heated, deposits a brown powder, while leucine and indiglucin remain in solution, together with certain volatile products, viz. carbonic, formic, acetic, and perhaps propionic acid, which escape when the liquid is heated.

The substance insoluble in water is a mixture of six different bodies. On exhausting it, first with cold, then with warm dilute soda-ley, *indikumin*, *indifuscin*, and *indiretin* are dissolved; the residue yields to alcohol, *α-* or *β-indifulvin* and *indirubin*, together with residues of indifuscin, while *indigo-blue* remains in solution. Instead of indifuscin, *indifuscone* is sometimes obtained. Schunck gives the following formulæ:—

a. Formation of indigo-blue or its isomer, indirubin, and of indiglucin:

$$\underset{\text{Indican.}}{C^{26}H^{31}NO^{17}} + 2H^2O = \underset{\text{Indigo-blue.}}{C^8H^5NO} + \underset{\text{Indiglucin.}}{3C^6H^{10}O^5}$$

Digitized by Google

Part of the indigo-blue is said to split up into leucine, formic acid, and carb anhydride:

$$\underset{\text{Indigo-blue.}}{C^{8}H^{5}NO} + 5H^{2}O = \underset{\text{Leucine.}}{C^{6}H^{13}NO^{2}} + \underset{\text{Formic acid.}}{CH^{2}O^{2}} + CO^{2}$$

b. Formation of *α*-indifulvin, indiglucin, and formic acid:

$$2C^{26}H^{31}NO^{17} + 5H^{2}O = \underset{\alpha\text{ Indifulvin.}}{C^{22}H^{20}N^{2}O^{3}} + \underset{\text{Indiglucin.}}{4C^{6}H^{10}O^{6}} + \underset{\text{Formic acid.}}{6CH^{2}O^{2}}$$

c. Formation of *β*-indifulvin, indiglucin, formic acid, and carbonic acid:

$$\underset{\text{Indican.}}{4C^{26}H^{31}NO^{17}} + 7H^{2}O = \underset{\beta\text{ Indifulvin.}}{C^{44}H^{38}N^{4}O^{3}} + \underset{\text{Indiglucin.}}{8C^{6}H^{10}O^{6}} + \underset{\text{Formic acid.}}{10CH^{2}O^{2}} + 2CO$$

d. Formation of indihumin, indiglucin, propionic acid, and carbonic anhydride

f. Formation of indiretin, indiglucin, carbonic anhydride, and water:

$$\underset{\text{Indican.}}{C^{26}H^{31}NO^{17}} = \underset{\text{Indiretin.}}{C^{16}H^{17}NO^{5}} + \underset{\text{Indiglucin.}}{C^{6}H^{10}O^{6}} + 2CO^{2} + 2H^{2}O$$

INDICANIN. $C^{20}H^{23}NO^{12}$. (Schunck, Phil. Mag. [4] xv. 183.)—This pound is produced, together with indiglucin, by the action of aqueous alkalis or ba water on indican:

$$C^{26}H^{31}NO^{17} + H^{2}O = C^{20}H^{23}NO^{12} + C^{6}H^{10}O^{6}.$$

Indicanin is left in contact with baryta-water; the liquid is precipitated with d sulphuric acid; and the filtrate is freed from excess of sulphuric acid by carbon lead, from lead by sulphydric acid, and evaporated in a stream of air at mean tem ture. The residue is dissolved in alcohol; the solution is mixed with twice its vo of ether, which precipitates indiglucin; and the filtrate is left to evaporate.

Indicanin is a yellow or brown bitter syrup, soluble in *water*, *alcohol*, and When heated on platinum-foil, it swells up strongly and leaves charcoal. By dry tillation it yields a brown oil in which white needles form. When boiled with it yields indiglucin and indirubin, and if impure, likewise indiretin and indifu Formation of indirubin:

$$C^{20}H^{23}NO^{12} + H^{2}O = C^{8}H^{5}NO + 2C^{6}H^{10}O^{6}.$$

When boiled with *soda-ley*, it gives off ammonia.

Aqueous indicanin forms a slight precipitate with neutral acetate of *lead*; alcoholic indicanin an alcoholic solution of neutral acetate of lead throws down a co sulphur-yellow precipitate, soluble in excess of the lead-acetate, precipitable by monia, and containing $C^{20}H^{23}NO^{12}.3Pb^{2}O$.

INDIFULVIN. (Schunck, *loc. cit.*)—This name is applied to two compou distinguished as *α* indifulvin, $C^{22}H^{20}N^{2}O^{3}$, and *β* indifulvin, $C^{44}H^{38}N^{4}O^{3}$, which obtained, together with indifuscin, indiglucin, indigo-blue, indihumin, indiretin, indirubin, by treating indican with dilute acids.

Preparation.—Indican is heated with dilute sulphuric acid; the flocks which rate are collected (the solution which runs off being preserved for the preparati indiglucin), washed with cold water, and treated, first with cold, then with warm d soda-ley, which dissolves one portion, and leaves another containing *α*- and *β*-indifu indirubin, and indigo-blue. The alkaline solution is precipitated with hydroch acid, and the precipitate is collected, washed, and treated with boiling ammonia, w dissolves indifuscin and indiretin, and leaves indihumin. The ammoniacal solu neutralised with acetic acid, yields a precipitate of indifuscin, and an additi quantity of this product is precipitated from the filtrate by alcoholic sugar-of-lead. indiretin which still remains in solution is separated by ammonia, in combination lead-oxide and contaminated with indifuscin; it is separated from the lead-oxid treating the precipitate with acetic and then with hot hydrochloric acid, and pur by repeated solution in alcohol, which leaves the indifuscin undissolved.

The mixture of *α*- and *β*-indifulvin, indirubin, and indigo-blue, insoluble in d soda-ley, gives up to boiling alcohol everything excepting the indigo-blue. The pu brown alcoholic solution, mixed with ammonia and alcoholic sugar-of-lead, dep residues of substances soluble in soda-ley; and on separating these, then adding ex of acetic acid, distilling off the alcohol, and diluting largely with water, purple-b flocks are obtained, from which, when purified with dilute soda-ley, a small quanti cold alcohol extracts indifulvin. On boiling the residue with an alkaline solutio protochloride of tin, filtering hot, and exposing the filtrate to the air, a purpl

Digitized by Google

deposit is formed, consisting of indirubin. This is washed with water and dissolved in alcohol. The portion insoluble in the alkaline solution is a mixture of indirubin and indifulvin.

Indifulvin is obtained of various composition, *α* or *β*, according to circumstances not well understood. It is a brittle, friable, reddish-yellow resin, which, when heated, melts, burns with flame, and leaves charcoal. Heated in a glass tube, it gives off a strong-smelling vapour, condensing to a brown oil, which solidifies in the crystalline form. Dissolves in strong *sulphuric acid*, with green-brown colour, and chars when heated. By ordinary *nitric acid*, it is scarcely attacked, even at the boiling heat; but it dissolves in fuming nitric acid, and is precipitated by water in orange-yellow flocks. By heating and evaporating the liquid, a yellow resin is obtained, together with crystals soluble in water, and different from oxalic acid. It is slowly decomposed by *chromic acid*. It does not dissolve in aqueous *alkalis*, even at the boiling heat, or on addition of grape-sugar, or dichloride of tin.

INDIFUSCIN, $C^{34}H^{20}N^2O^8$, and **INDIFUSCONE**, $C^{32}H^{20}N^2O^8$?—These compounds are produced in greatest quantity by the action of dilute sulphuric acid on indican which has been previously exposed to the air. A brown powder is then formed, containing from 59·4 to 67·5 per cent. C, 5·78 to 7·12 N, and 29·12 to 20·23 O, so that it appears to agree, sometimes with one, sometimes with the other of the formulæ just given. When heated, it emits vapours, with an odour of burning turf, and yields an oily distillate. It burns without fusion; colours *chromic acid* green; with boiling *nitric acid*, it yields oxalic and picric acids; dissolves in strong sulphuric acid, with brown colour, giving off sulphurous anhydride when heated. It is insoluble in boiling water; dissolves easily in alcoholic *ammonia*, whence it is precipitated in brown flocks by acids; also in aqueous *alkalis* and *alkaline carbonates*, and is precipitated therefrom by *metallic salts*; sparingly soluble in boiling *alcohol*.

INDIGLUCIN. $C^6H^{16}O^6$. (Schunck, Phil. Mag. [4] x. 73; xv. 183; Jahresber. 1856, 659; 1858, 465; Gm. xv. 302.)—Produced, together with the products above mentioned, by heating indican, indicanin, oxindicanin, or oxindicasin, with water, acids, or alkalis (pp. 247, 248).

Preparation.—Tincture of woad-leaves, prepared with cold alcohol, is evaporated in a current of air; the residue is mixed with cold, very dilute sulphuric acid, and the fat which falls to the bottom is immediately separated by filtration. The filtrate serves instead of the acidulated aqueous solution of indican. The decomposition, which begins in the cold, is kept up by gentle heating, whereupon the solution becomes turbid, and a mixture of six insoluble substances separates (p. 247); the liquid is then filtered, the residue washed with cold water, and decomposed in the manner described under indican. The filtrate, freed from sulphuric acid by carbonate of lead, and from lead by sulphuric acid, evaporated to a syrup in a stream of air, dissolved in alcohol, and mixed with a large quantity of ether, deposits leucine in crystals, and indiglucin as a syrup. The latter, after the removal of the crystals, is dissolved in water; the solution is mixed with acetate of lead; the scanty precipitate is removed; and the yellow lead-compound of indiglucin is precipitated from the filtrate by aqueous ammonia. The lead-salt decomposed by sulphydric acid under water, and treated with animal charcoal till a sample gives a white precipitate with ammoniacal sugar-of-lead, yields a solution from which, by evaporation, solution of the residue in alcohol, and addition of ether, the indiglucin is precipitated in the form of a syrup.—2. In the preparation of indicanin from indican, by mixing the latter with baryta-water and leaving it at rest, then removing the baryta, evaporating the filtrate in a current of air, dissolving the residue in alcohol, and precipitating by ether, indiglucin is separated as a syrup. This syrup is dissolved in alcohol, mixed with excess of alcoholic sugar-of-lead, the brown precipitate removed, and the solution precipitated with ammonia. The lead-compound of indiglucin is purified and decomposed as in method 1.

Indiglucin is a colourless or light yellow syrup having a slightly sweet taste, soluble in *water* and in *alcohol*, but precipitated from the alcoholic solution by *ether*.

It swells up when heated, and gives off an odour of caramel. With boiling *nitric acid*, it forms oxalic acid. With strong *sulphuric acid*, it becomes carbonised. When boiled with *soda-ley*, it turns yellow, and separates brown flocks. From an *alkaline cupric solution* it reduces cuprous oxide; from an aqueous and still more from an *ammoniacal* solution of *nitrate of silver*, it reduces metallic silver; similarly with *trichloride of gold*. It is not fermentable, but turns acid by prolonged contact with *yeast*.

Aqueous indiglucin dissolves *hydrate of calcium*, and the solution on boiling deposits copious yellow flakes, which dissolve on cooling, and are precipitated by alcohol. From a mixture of indiglucin with *baryta-water* alcohol throws down yellow flakes.—Aqueous indiglucin is precipitated by neutral or basic acetate of *lead*, only after addition of ammonia; the precipitate has the composition $C^{12}H^{18}Pb''O^{12}.3Pb''O$.

Digitized by Google

INDIGO-BLUE. C^8H^5NO or $C^{16}H^{10}NO^2$.—*Blue Indigo. Indigotin. Oxidized Indigo* (Gm. xiii. 35; Gerh. iii. 514).—This important colouring matter was known in India and in Egypt before the Christian era, and is mentioned by Dioscorides and Pliny under the names *ἰνδικόν* and *indicum*. Egyptian mummies have been found wrapped in blue cloths, the colour of which exhibited all the characters of indigo. The Romans used it only as a pigment, not being acquainted with the method of dissolving it. Its introduction into Europe as a dye is generally attributed to the Jews, who during the middle ages practised the art of dying with indigo in the Levant. It was first imported in large quantities into the European markets from India in the seventeenth century by the Dutch.

Indigo is chiefly obtained from various species of *Indigofera*, namely, *I. tinctoria*, *I. Anil*, *I. disperma* and *I. pseudotinctoria*, cultivated especially in the East and West Indies; also from *Nerium tinctorium* and *Calanthe veratrifolia*, natives of Hindostan; *Asclepias tinctoria* and *Marsdenia tinctoria* of Sumatra, *Polygonum tinctorium*, *Isatis indigotica*, *Justicia tinctoria* and *Bletia Tankervillia* of China, and *Amorpha fruticosa* of Carolina. The only European plant which yields true indigo-blue is woad (*Isatis tinctoria*), which was extensively used for blue-dyeing before the introduction of indigo; but it is much less rich in indigo than the tropical plants above mentioned, and is now used only as an addition to the indigo-vat (p. 252). The following European plants also yield blue colouring matters more or less resembling indigo, but apparently not identical with it: *Astragalus glycyphyllus*, *Centaurea Cyanus*, *Chelidonium majus*, *Cicer arietinum*, *Colutea arborescens*, *Coronilla Emerus*, *Galega officinalis*, *Hedysarum Onobrychis*, *Inula Helenium*, *Iris germanica*, *Lotus corniculatus*, *Medicago sativa*, *Mercurialis perennis*, *Polygonum aviculare*, *Polygonum Fagopyrum*, *Rhinanthus Crista-galli*, *Sambucus nigra*, *Sambucus Ebulus*, *Scabiosa succisa* and *Vaccinium Myrtillus*.

Indigo-blue is sometimes deposited from human urine both healthy and diseased, being produced by spontaneous fermentation from indican (p. 246). It has also been occasionally observed to form in the milk of cows, especially such as have been fed exclusively on sainfoin.

With regard to the state in which indigo exists in the plants from which it is obtained, and the nature of the process by which it is converted into indigo-blue, various opinions have been entertained. Roxburgh (*Transactions of the Society of Arts*, vol. xxviii.) supposed that indigo plants contain only the base of the colouring matter, which of itself is green; that it is kept in solution by the carbonic acid evolved in the preparation of indigo, set free by the addition of alkalis, and absorbs from the air a substance which converts it into indigo-blue. Giobert (*Traité sur le pastel*, Paris 1813) supposed that indigo-plants contain colourless indigogen, which is soluble in water and contains more carbon than indigo-blue, into which it is converted, with formation of carbonic acid, by absorbing oxygen from the air. This oxidation is promoted by heat or by the presence of alkalis, especially by lime; it is arrested by acids, even by carbonic acid. (Giobert.)

According to Chevreul (Ann. Chim. lxvi. 8; lxviii. 284), woad and other indigo-plants contain indigo-white, C^8H^6NO, which contains 1 at. H more than indigo-blue, and being held in solution by the sap, is converted into indigo-blue by oxidation, on exposure to the air:

$$2C^8H^6NO + O = 2C^8H^5NO + H^2O.$$

This explanation, being the simplest, was very generally adopted, until Schunck (Phil. Mag. [4] xv. 29) pointed out that white indigo cannot exist in any plant, since it requires free alkali for its solution, whereas the sap of plants is always acid, and moreover contains free oxygen. Schunck has further shown that woad contains indican, (p. 246), which is readily soluble in water, and when boiled with acids splits up into indigo-blue and indiglucin, without the intervention of oxygen:

$$\underset{\text{Indican.}}{C^{26}H^{31}NO^{17}} + 2H^2O = \underset{\text{Indigo-blue.}}{C^8H^5NO} + 3\underset{\text{Indiglucin.}}{C^6H^{10}O^5}.$$

The same substance probably exists in other indigoferæ, and in other plants from which indigo is obtained, and during the steeping process, presently to be described, is resolved, in consequence of the fermentation which takes place, into indigo-blue and indiglucin.

Preparation of Commercial Indigo.—1. *From fresh leaves.*—In Bengal, the plants, which are cut close to the ground whilst the blossom is unfolding, are placed in a brick cistern (*steeping vat, Gährungsküpe, trempoire, pourriture*), which is filled several inches deep with cold water, and allowed to ferment. At 30° C. (86 F.) the fermentation is finished in from 12 to 15 hours; at lower temperatures it requires a longer time. The gas evolved is a mixture of carbonic anhydride and atmospheric air from which the

Digitized by Google

oxygen has been absorbed. When the liquid no longer rises, it is drawn off into the *beating vat* (*Schlagekūpe, batterie*) which stands lower, where it is kept stirring for an hour and a half or two hours, whereupon carbonic anhydride is evolved and the indigo at first separates in large flakes. When, after being repeatedly stirred, it forms grains like fine sand, and the solution is clear, the indigo is allowed to settle. After two or three hours, the liquid is drawn off from the deposit. If the fermentation is properly conducted, the indigo settles readily down, the liquid is of a malaga-brown colour, and forms a thick foam which rapidly disappears. The deposit is boiled for three or four hours in a copper vessel and then thrown upon a linen filter; it is afterwards pressed, cut into squares, and dried by heat. 1000 pts. of the solution of the leaves yield from 0·5 to 0·7 pts. of indigo; more is precipitated on the addition of potash-ley or lime-water, but it is not so pure.

Respecting the manufacture of indigo in the Caucasus, see *Dingl. pol. J.* 126, 304.

2. *From dry leaves.*—In the southern parts of India, the leaves of the indigo plant are dried, and packed up for a month, more or less, at the expiration of which time they assume a light lead colour; by additional keeping the lead-colour gradually darkens till it becomes black. Experience has proved that the leaves will not give out any colouring matter to cold water till the first change has commenced, when the maximum quantity of indigo seems to be developed; and that from this period it diminishes. If from fear of rain the plant be cut too soon, the leaves should be kept proportionally longer; but if, from want of sufficient sunshine, the cutting be deferred till after the plant is fully ripe, the leaves will not require to be kept so long.

These leaves, after due keeping, are transferred to the steeping-vat, where they are infused in water, in the proportion of about one volume of leaves to six of water, and allowed to digest for two hours, with occasional stirring. The water is then run off through strainers into the beating-vat, where it is agitated by the paddles of ten or twelve natives for about two hours, during which time the fine green liquor gradually darkens to a blackish hue. Lime-water is now thrown into the vat, and well mixed with the liquor. The supernatant Madeira-coloured liquid is run off after repose, and the subsided blue indigo is drained on cloth. Next morning it is mixed with water in a copper and boiled; after which the whole is thrown on strainers, and the indigo collected is dried and formed into cakes. (Weston, *Journal of Scienos*, xxvii. 296.)

Indigo is obtained in the same way in the south of France from a hot extract of *Nerium tinctorium* and *Polygonum tinctorium* (J. Pharm. xxvi. 276; J. pr. Chem. xvi. 180). Indigo was formerly prepared from woad in a similar manner, by employing tepid water and precipitating with lime-water; a deeper colour was imparted to the product by extracting the carbonate of calcium with hydrochloric acid. The preparation of indigo from *Polygonum tinctorium* is rendered difficult by a resin which the plant contains. This resin is separated by mixing the bruised leaves with one-tenth of their weight of protosulphate of iron, and adding a sufficient quantity of water, together with an excess of carbonate of potassium; the whole is then thrown upon a filter, and the solution mixed with sufficient nitric acid to render it slightly acid. On neutralising with carbonate of potassium, it becomes blue and deposits all the indigo-blue within 24 hours; the indigo has then the same properties as that obtained from *Indigofera*. (Gaudry, N. J. Pharm. v. 133.)

Purification.—Commercial indigo contains from 50 to 60 per cent. of pure indigo-blue, the remainder consisting of indigo-gluten, indigo-red, indigo-brown, and a number of brown resinous products, &c., formed either by decomposition of the indigo-blue produced in the first instance, or directly from the indican itself (p. 246). Certain substances are also occasionally added to indigo for the purpose of adulteration.

Indigo may be purified from most of these foreign matters by treating it successively with dilute sulphuric or hydrochloric acid, with boiling water, and with alcohol. This treatment however does not yield a chemically pure product, and it is better to resort to the process of the vat, which consists in converting the indigo-blue into indigo-white by the action of reducing agents, and subsequently reoxidising it. This process is also one of great industrial importance, being that which is used by dyers for rendering indigo soluble and fixing it upon tissues.

a. Cold Vats.—1. *Copperas* or *common blue vat.* (*Cuve à la couperose, Vitriol-kūpe.*) In this, which is the kind of cold vat generally used for dyeing cotton, hemp, and flax, the indigo-blue is reduced by the action of protosulphate of iron. 1 pt. of finely ground indigo is mixed with hot water, in which 4 pts. of quick-lime are slaked; to this is added a solution of 3 pts. of sulphate of iron free from copper, the whole being stirred. (If the sulphate of iron is yellowish, one-third more is taken.) Water is added, to the amount of 100 or 200 times the weight of the sulphate of iron, according as the dye is required dark or light, and the whole, after being stirred, is left at rest. The proportions quoted are those most commonly used in dyeing; when the indigo is particularly pure, more lime and sulphate of iron must be taken. An excess of lime

Digitized by Google

yields a *sharp* vat (*scharfe Küpe*), from which the threads of the material readily take up the dye; too little lime yields a *soft* vat (*leise Küpe*), which dye so well. On the addition of carbonate of potassium, a compound of indi with potash is formed. A sediment is formed and a yellow solution, which covered with a copper-coloured film (flower); the solution is drawn off f sediment, and deposits tolerably pure indigo-blue on exposure to the air.—Th digests commercial indigo with lime, sulphate of iron, and water, and expose air the decanted solution of the compound of indigo-white with lime; he then the carbonate of calcium from the blue precipitate with hydrochloric acid, indigo-red with water, afterwards washes with water and dries.—Berzelius mix of indigo (purified according to 1) with 6 pts. of quick-lime freshly slaked, 4 sulphate of iron, and 450 pts. of boiling water; he then closes the vessel and repeatedly; allows the whole to subside, and removes the yellow solution by me siphon; again adds hot water, and draws it off after repeated shaking; and m whole of the solution with hydrochloric acid; this is exposed to the air and sh the indigo is completely oxidised; it is then thrown on a filter and washed wit —Erdmann mixes together 1 pt. indigo, 2 pts. sulphate of iron, 3 pts. li 60 pts. water; draws off the clear solution; mixes it, stirring repeatedly, wit hydrochloric acid; and washes the precipitate in contact with the air. The residu fresh quantities of indigo-blue when again stirred up with hot water, and with necessary. The indigo-blue thus obtained contains a little gypsum, at most cent., and indigo-red, which it is difficult to remove by boiling with alcohol; it to reduce the indigo again in the cold vat and precipitate it with hydrochloric According to Dumas, a little sulphide of calcium is formed in the vat, and hence is mixed with the indigo when it is precipitated by hydrochloric acid; this he with sulphide of carbon.

2. In the so-called *orpiment-vat*, a solution of the compound of indigo-wh potash is formed in a mixture of indigo-blue with trisulphide of arsenic, pot water, by the oxidation of the resulting sulpharsenite of potassium; the deposits indigo-blue when exposed to the air. This kind of vat is chiefly calico-printing, not for dyeing properly so-called.

3. In the *tin-vat*, commonly used for calico-printing, the indigo is reduc solution of stannous oxide in caustic potash or soda. The bath is usually mi an acid solution of tin, so as to neutralise the alkali and precipitate the indig the precipitate is then used for printing.

b. Warm vats.—1. *Woad-vat.* (*Pastel-vat.*) On mixing from 2 to 6 finely powdered indigo with from 30 to 50 pts. woad, 2 pts. madder, 2 pts. b 8 pts. potash, and ½ pt. lime, and warming with 1000 pts. water (6000 to 700 at 80° C. (176° F.), a fermentation is set up in which water is decomposed nascent hydrogen forms indigo-white, which combines with the ammonia taneously formed. The brownish-yellow liquid first becomes green on exposu air, and then deposits indigo-blue; it may be used for dyeing for three to six mon vided it be kept warm, and madder, bran, indigo or potash added from time to required. Beetroot-molasses and malt may be advantageously used instead of

The use of madder, bran, &c. in this process appears to depend upon the gu amylaceous substances and the pectic acid which they contain. These substa probably transformed, first into lactic, then into butyric acid, in which transfo hydrogen is evolved, which reduces the indigo-blue to indigo-white. The woa same time undergoes putrefaction, and gives off ammonia, which keeps the white in solution. The lime seems to act chiefly by neutralising the excess produced by the decomposition of the amylaceous and gummy matters.

2. In the *potash* or *Indian vat*, in which woad and lime are not used, 3 pts. c are added to a mixture of 2 pts. madder, 2 pts. wheat-bran, 6 pts. potas 1000 pts. water at 60° C. (140° F.); after 36 hours, 3 pts. potashes, and after more the same quantity of potashes, are likewise added. This vat is easier to than the woad vat.

3. The *urine-vat* is employed only in small dye-houses and in certain loca at Verviers, for the dyeing of wool. The putrefying urine furnishes at once the agents to convert the blue into white indigo, and the ammonia necessary to the latter. [For further details respecting the manufacture of indigo and it dyeing, see *Ure's Dictionary of Arts, &c.* ii. 498.]

To obtain indigo-blue in the crystalline state, 4 oz. of raw indigo and 4 oz. sugar are introduced into a flask capable of containing 12 lbs. water, to which the strongest soda-ley are added. The whole is well shaken, and the flask co filled with hot alcohol; it is then tightly corked and allowed to stand for sever until the solution is sufficiently clear to permit its being siphoned off into flask. The flask is allowed to stand loosely covered; the solution, at first of a

Digitized by Google

yellowish-red colour, now gradually turns blue, whilst indigo separates out. The solution is filtered and the indigo is washed, first with alcohol and then with water, till the filtrate is colourless. In this manner, 2 oz. (50 per cent.) of pure indigo-blue is obtained. If the brown alcoholic solution is poured back hot into the first flask, it yields 3 per cent. more indigo; but it is then nearly exhausted (Fritzsche, Marchand).—Indigo also forms a vat immediately with grape-sugar, caustic soda, and hot water; the decanted solution, when exposed to the air, deposits indigo-blue containing a quantity of indigo-red, which may be extracted by an alcoholic solution of soda. (Fritzsche.)

Purification of indigo by sublimation.—When powdered commercial indigo is heated on a watch-glass, a silver dish, or a spoon, a network of crystals is formed, which may be removed with a pair of forceps, and the crystals carefully separated from adhering particles of carbon, under a magnifying glass (Le Royer and Dumas; Dumas).—Crum heats indigo between two platinum crucible lids, which are separated from one another by a distance not greater than $\frac{3}{4}$ inch, till the hissing sound ceases.—Berzelius sublimes indigo in an exhausted retort, of the size of a chicken's egg, cuts off the upper part of the retort when the crystals have sublimed, and separates the lower crystals from the adhering particles of carbon. The crystals are freed by ether from traces of oil and resin.—Taylor stirs up an intimate mixture of 2 pts. finely powdered indigo and 1 pt. gypsum with water into a thin paste, which he spreads upon sheet iron in layers 2 inches broad and $\frac{1}{8}$ inch deep. These are dried by exposure to the air, then heated at one end with a spirit-lamp till red vapours are evolved, and so the operation is continued. If the mass catches fire, it is extinguished by a drop or two of water. The velvety indigo can easily be separated, and may be purified by alcohol and ether. (Med. Gaz. 1843, 130.)

Preparation of Indigo-blue from Indican.—The aqueous solution of indican from woad-leaves, which must not be too dilute, is boiled with sulphuric acid or hydrochloric acid; and the abundant purple-blue precipitate is filtered off and washed, first with water and then with boiling alcohol, till the filtrate is of a pure blue colour: the residue consists of pure indigo-blue. Nitric, oxalic, tartaric, and acetic acids are also capable of converting indican into indigo-blue: acetic acid, however, acts less powerfully than the rest. (Schunck.)

Properties.—Indigo-blue sublimes in right rhombic prisms (Miller); in six-sided prisms derived from a rhombic prism of 32° and 148°, and having their bases replaced by two faces which seem to form an obtuse angle with one another (Laurent). Its lustre is semi-metallic, and by reflected light, dark-red inclining to copper-red (according to Crum, it is red when viewed obliquely under the microscope; and of a brilliant blue when viewed perpendicularly). When prepared in the wet way, it is dark blue, and acquires by pressure a dark copper colour and almost metallic lustre. It is inodorous and tasteless, and does not react upon vegetable colours.—In open vessels, it volatilises at about 288° in dark purple-red vapours; in closed vessels, it decomposes partially when heated (Crum). It volatilises without decomposition only in a current of air or in vacuo; the powder dropped on a piece of heated platinum foil, volatilises in purple vapours without leaving a residue, each particle being supported by the vapour without coming in contact with the foil (Dumas). It is quite insoluble in *water*, dilute *acids*, and *alkalis*, *ether*, and *volatile oils*; also in *alcohol* and *fixed oils* at common temperatures; but hot alcohol, and fixed oils heated above 100°, dissolve small quantities, and deposit it again on cooling. Sublimed indigo dissolves pretty readily in hot *phenic acid*, forming a blue liquid when mixed with a little alcohol, but precipitated by a larger quantity. Sublimed indigo also dissolves to a small extent in hot *oil of turpentine*.

Indigo-blue is isomeric with cyanide of benzoyl.

Decompositions.—1. Indigo-blue melts and boils when heated in contact with the *air*; at higher temperatures it burns with a bright and very smoky flame, leaving a residue of difficultly combustible charcoal (Berzelius). By exposure to air containing *ozone* it is quickly converted into isatin. (Erdmann, J. pr. Chem. lxxi. 209.)

2. By dry distillation, it yields a very little undecomposed sublimate, together with carbonate and cyanide of ammonium, phenylamime, empyreumatic oil, and a large residue of shining charcoal (Crum). On heating indigo-blue in vacuo, a brown oil is formed, together with a large proportion of sublimed indigo, but no permament gas or aqueous liquid; by rapid heating, more sublimate is obtained, and a fused shining charcoal; on heating more gradually, less sublimate is formed, together with a dull earthy charcoal. (Berzelius.)

3. Dry *chlorine* does not act upon indigo-blue between 0° and 100°. If indigo-blue is stirred up with water into a thin paste, and chlorine passed through while the whole is kept cool, the mass becomes first greyish-green and then yellow. Neither carbonic anhydride nor any other gas is evolved. An orange-coloured deposit is

Digitized by Google

formed, and a yellowish-red solution; on distilling, trichlorophenic acid and trichlorophenylamine sublime, and a liquid distils over which smells of anisic acid, and contains hydrochloric and trichlorophenic acids. The residue in the retort dissolves in boiling water, leaving a brown resin, which is formed in small quantity only. If the mass is cooled as much as possible during the action of the chlorine, and the passage of the chlorine is interrupted before all the indigo-blue is destroyed, the boiling aqueous solution deposits, on cooling, a yellowish-red crystalline powder, which yields chlorisatin and dichlorisatin when recrystallised from alcohol. (Erdmann.)

4. *Bromine* acts upon indigo in the same manner as chlorine. On treating moist indigo with bromine, a yellow mass is formed, which yields, by distillation, tribromophenic acid and tribromophenylamine; the residue contains a little bromisatin, a large proportion of dibromisatin, and a little resinous matter. (Erdmann.)

5. *Iodine* decomposes indigo only when heated. (Berzelius.)

6. Indigo is decomposed by heating it with *chlorate of potassium* and *hydrochloric acid*. Only traces of chloranil are formed. (Hofmann.)

7. When boiled with dilute *nitric acid*, it gives off a large quantity of gas, and forms isatin and a brown resin; with a stronger acid, it forms principally nitrosalicylic acid, and with an excess of nitric acid of specific gravity 1·43, it yields picric acid; at the same time carbonic anhydride, prussic acid, oxalic acid, and the so-called artificial indigo-resin are formed. 5 pts. of fuming nitric acid becomes so violently heated with 1 pt. powdered commercial indigo that the mass takes fire.

8. Concentrated *chromic acid* destroys indigo-blue immediately, especially when heat is applied, with violent evolution of carbonic anhydride and precipitation of sesquioxide of chromium. Dilute chromic acid forms a clear yellow-brown solution with indigo; if this is heated to near the boiling point and filtered, isatin crystallises out on cooling (Erdmann). Chlorochromic acid does not act upon indigo-blue. (Thomson.)

9. On boiling indigo-blue with *peroxide of lead*, a pale yellow solution is formed, which becomes turbid on cooling, and leaves a yellow powder when evaporated to dryness. This substance being suspended in water and decomposed with sulphydric acid, yields a brownish-yellow filtrate, which on evaporation leaves a residue consisting of a small quantity of brown resin and a few crystals. The sulphide of lead contains a brown resin, melting at 100°, which may be extracted by boiling alcohol, and precipitated by water; boiling water extracts from it a substance which, on evaporation, deposits crystals mixed with resin. (Erdmann.)

10. *Manganic sulphate*, *manganate of potassium*, and *permanganate of potassium* decolorise indigo (Lefort, Rev. scient. 16, 358). On heating indigo-blue for a considerable time with aqueous *osmic acid*, oxalic acid is formed. (Buttlerow, J. pr. Chem. lvi. 278.)

11. When the vapour of *sulphuric anhydride* is passed over roughly pulverised commercial indigo, the latter swells up, becomes heated, and a beautiful purple-red liquid is formed, which is transparent in thin layers, and solidifies into a crimson mass. In contact with the air, it evolves sulphurous anhydride (probably on account of the impurities of the indigo), and dissolves in common sulphuric acid with a violet colour; on dissolving it in water, charcoal separates out and a dark blue solution is formed (Döbereiner; Bucholtz; Bussy). Indigo dissolves, with evolution of heat, in excess of fuming or of common *sulphuric acid* (no gas is evolved if the indigo is pure) with formation of sulphindigotic acid; if an excess of sulphuric acid is not added, more or less sulphophœnicic acid is formed. According to Berzelius, hyposulphindigotic acid is also formed when indigo is dissolved in fuming sulphuric acid. Indigo-blue dissolves in cold sulphuric acid, first with a yellow colour, which afterwards becomes green, and finally of a beautiful blue (Housmann, Journ. de Phys. 1788; March, Chevreul). From the solution, while still yellow, undecomposed indigo-blue may be precipated by water; the yellow colour changes to blue in a few hours in a closed vessel, since sulphophœnicic acid is formed, which is gradually converted into sulphindigotic acid. When indigo is more strongly heated with sulphuric acid, sulphurous anhydride is evolved, and a brown oily liquid formed (Döbereiner). Liquid sulphurous anhydride does not act upon indigo (Bussy). Phosphoric anhydride and hydrated phosphoric acid are without action upon indigo; also concentrated hydrochloric acid. (Döbereiner.)

12. Indigo-blue is but slightly attacked by prolonged boiling with dilute *potash*; when the boiling point has reached 100°, the indigo is completely decomposed, whilst no gas is given off, and only traces of ammonia and phenylamine are evolved with the aqueous vapour (Fritzsche). According to Gerhardt (Rev. scient. x. 371), indigo-white and isatate of potassium are formed in this reaction:

$$\underset{\text{Indigo-blue.}}{3C^8H^5NO} + KHO + H^2O = \underset{\text{Indigo-white.}}{C^{16}H^{12}N^2O^2} + \underset{\text{Isatate of potassium.}}{C^8H^6KNO^3}$$

Digitized by Google

According to Fritzsche, a yellowish-red solution is first formed, on which a dark coloured substance floats, and from which yellow crystals of chrysanilate potassium are separated by continued boiling; on cooling, it solidifies into a crystalline mass, consisting principally of chrysanilate of potassium. The crystalline mass, when water is poured over it, immediately yields indigo-blue (in the same state as from the indigo-vat); the filtered solution also continues to deposit indigo-blue when exposed to the air. According to Gerhardt, Fritzsche's chrysanilic acid is nothing but a mixture of isatin, indigo-white, and perhaps also other products resulting from the further action of the potash. The indigo-blue is formed by oxidation of the indigo-white.

Indigo-blue fused with *hydrate of potassium* yields first isatic acid, as above, then phenylcarbamic acid resulting from the decomposition of the latter. (Gerhardt.)

$$\underset{\text{Isatic acid.}}{C^9H^7NO^3} + H^2O = \underset{\substack{\text{Phenyl-car-}\\\text{bamic acid.}}}{C^7H^7NO^2} + CO^2 + H^2,$$

and by further decomposition, salicylic acid (Cahours) and phenylamine (Fritzsche):

$$\underset{\substack{\text{Phenyl-car-}\\\text{bamic acid.}}}{C^7H^7NO^2} + H^2O = \underset{\substack{\text{Salicylic}\\\text{acid.}}}{C^7H^6O^3} + NH^3$$

$$\underset{\substack{\text{Phenyl-car-}\\\text{bamic acid.}}}{C^7H^7NO^2} = \underset{\substack{\text{Phenyl-}\\\text{amine.}}}{C^6H^7N} + CO^2$$

13. Indigo-blue placed in contact with water, an *alkali*, and a *deoxidising substance*, becomes at first coloured green, and is then converted into indigo-white, which forms a yellow solution with alkalis. In this reaction, water is decomposed, the hydrogen being used in the formation of indigo-white, *e. g.* with *stannous oxide*:

$$\underset{\text{Indigo-blue.}}{2C^8H^5NO} + SnO + H^2O = \underset{\text{Indigo-white.}}{C^{16}H^{12}N^2O^2} + SnO^2$$

The following substances react in a similar manner: phosphorus, phosphorous acid, sulphurous acid, sulphydric acid, potassium-amalgam, sulphide of potassium, sulphide of sodium, sulphide of arsenic, sulphide of antimony, zinc, tin, iron, ferrous, stannous, and manganous oxides, grape-sugar, and substances undergoing fermentation or putrefaction, as sugar, gluten, urine, woad, madder. Warm putrid urine dissolves indigo-blue, the ammonia-compound of indigo-white being formed. According to Löwenthal, on the contrary (J. pr. Chem. lxx. 463), this reduction of blue to indigo-white is not produced by salts of sulphurous or phosphorous acid, by sulphide of potassium, sulphide of calcium, manganous salts, or arsenite of sodium; but indigo-blue dissolved in sulphuric acid is reduced to indigo-white, when mixed with excess of acid carbonate of potassium or sodium, and then treated with sulphydric acid. Löwenthal is of opinion that indigo-white is not indigo-blue *plus* hydrogen, but indigo-blue *minus* oxygen.

Testing and Valuation of Indigo.—Commercial indigo occurs in small lumps or cubic loaves of a violet-blue colour; when of good quality it is very light; assumes a coppery aspect when rubbed with a hard polished body; and is free from flaws or cavities traversed by brown or whitish veins. The best sorts are light enough to float on water.

External characters, however, give but very uncertain indications of the amount of real colouring matter contained in a sample of indigo; hence it becomes necessary to resort to chemical methods of estimating the amount of pure indigo-blue. Good sorts of indigo contain about 60 per cent., but the proportion is often much reduced by fraudulent admixture of foreign substances, such as sand, vegetable mould, powdered lead, starch, &c. Some foreign matters are also unavoidably introduced in the process of manufacture.

The indigo is first dried over the water-bath to estimate the hygroscopic water; which, in samples not fraudulently moistened, varies from 3·5 to 6 per cent. The dried indigo is then calcined in a platinum crucible to determine the amount of ash. Good indigo generally yields from 7 to 10 per cent. The presence of sand, lead-powder, &c., may then easily be detected by washing the ash with water.

The presence of starch, sometimes coloured with iodine, is indicated by the pale colour, greater density, and friability which it imparts to the lumps of indigo. It may be further detected by treating the indigo with slightly alkaline water, neutralising the filtered liquid with a few drops of acid, and testing with iodine.

The older methods of estimating the proportion of real indigo-blue in commercial indigo depend, for the most part, on the decoloration produced by chlorine and other oxidising agents.

1. *With chlorine water.*—A weighed quantity of the finely pulverised indigo is added by small portions to a measured quantity of a saturated aqueous solution of chlorine, as long as it dissolves with yellow colour, and the quantity thus dissolved is ascertained by weighing the residue. A similar trial is then made with perfectly pure indigo-blue,

Digitized by Google

and a comparison of the two results gives the proportion of colouring matter sample of commercial indigo under examination. As the strength of the chlorin alters very quickly, it cannot be titrated long beforehand. (Berzelius.)

2. *With chloride of lime.*—The indigo is first dissolved by digestion for five hours at 50° or 60° with fuming sulphuric acid; the solution is thoroughly mix distilled water, and poured into a graduated burette, and from this vessel it is drop by drop to a measured quantity of aqueous chloride of lime, till the blue just becomes permanent. A similar experiment being then made with an equal of pure indigo blue, the colouring power of the two samples is in the inverse r the quantities of the blue solution consumed in the two experiments. (Schlumb Bull. Soc. industr. de Mulhouse, vol. xv.)

3. With *hydrochloric acid and chlorate of potassium.*—1 grm. of finely pul indigo is digested for some hours with 10 grms. of fuming sulphuric acid, agitati time to time to assist the solution. The liquid is then poured into a basin con a kilogramme of water, 50 grms. of strong hydrochloric acid are added, and th is heated to the boiling point. On the other hand, 0·25 grm. of chlorate of po is dissolved in 100 grms. of water; and the solution is poured into a graduated and added drop by drop to the boiling indigo solution till the blue colour cha red-brown. The richness of the sample of indigo is directly proportional quantity of chlorate consumed. (Bolley, Ann. Ch. Pharm. lxxv. 242.)

4. With *sulphuric acid* and *acid chromate of potassium.* The mode of pro is the same as that just described; 10 grms. of pure indigo-blue prepared by Fri method require for decoloration exactly 7½ pts. of the acid chromate. (Penny, Soc. J. v. 297.)

All these methods are liable to the objection that it is difficult to institute a comparison between the different shades of colour resulting from the oxidation indigo in different cases, the pure green tint thus produced in solutions of pure blue giving place to a dirty olive or brownish-green when crude indigo is used, sequence of the impurities contained in it. Moreover, in dissolving indigo in sulphuric acid, it is scarcely possible to avoid the formation of sulphurous a presence of which will of course raise the apparent percentage of indigo-blue sample. By employing these methods indeed, it is common to find, in a good sa indigo, more than 80 per cent. of pure indigo-blue, whereas the best qualities contain above 60 per cent., and average qualities not more than 40 to 50 per c

The following methods, which depend upon the reduction instead of the oxid the indigo, give more exact results.

5. With *Protosulphate of Iron.*—A weighed quantity of the finely pulverised i well mixed with an equal weight of pure lime previously slaked with water. The is poured into a stoppered bottle of known capacity, and the mortar is well rins water, which is added to the rest. The bottle is now heated in a water-bath for hours, and a quantity of finely-powdered sulphate of iron is added; the bottle filled up with water; the stopper is inserted; and, after the contents have b shaken, the whole is left at rest for several hours, till the indigo is reduced sediment has sunk to the bottom. A portion of the clear liquor is then drawn a siphon, and the quantity of liquid having been accurately measured, it is mix an excess of hydrochloric acid, and the precipitate, after having been oxidised posure to the air), is collected on a weighed filter, and washed with water. the filter with the indigo-blue is dried at the heat of the water-bath, and weigh the weight of the filter having been subtracted from that of the whole, the of the indigo-blue is ascertained. Suppose, for example, that the whole qua liquid was 200 measures, and that 50 measures have been drawn off, yielding 1 of indigo-blue; then the total quantity of indigo-blue in the sample is 40 grain 60 grains of indigo it is necessary to take from 1 lb. to 2 lbs. of water. This though rather tedious, gives better results than any of the preceding. The of indigo-blue indicated by it is usually somewhat less than the actual quant tained in the sample.

6. With *stannous chloride.*—The tin-solution is titrated with a solution indigo-blue, prepared by dissolving the substance dried at 210°–230° C. (410°– in 16 pts. of strong sulphuric acid, with addition of pounded glass to divide th and facilitate the solution. The indigo-solution thus obtained is diluted wit till a litre of it contains exactly 1 grm. of indigo-blue. The indigo to be exa then dissolved in a similar manner, and the titrated tin-solution is added to i burette till the blue colour changes through green to light-yellow. Iron, if pr the indigo, must first be removed by digestion in hydrochloric acid, with ad pounded glass. (E. Mulder, Scheik. Onderz. iii. [1] 37; Jahresber. 1860, p.

7. With *zinc.*—A solution of indigo in sulphuric acid is dilute with w hydrochloric acid, and decolorised by zinc in an atmosphere of carbonic anhyd

When the fresh leaves of *Polygonum tinctorium* are exhausted with ether, and part of the ether is distilled off, indigo-blue separates out; and on evaporating the remaining solution to dryness, and exhausting the residue with alcohol, filtering from a slight brown residue, again evaporating to dryness, and exhausting the residue with hot water, which extracts a little yellow colouring matter, a hard brittle friable resinous substance separates of a fine red colour, and probably agreeing essentially with the red of common crude indigo. It is insoluble in *water*, slightly soluble in *potash*, *ammonia*, and *acetic acid*, easily in *alcohol* and *ether*. The alcoholic solution turns red on addition of *baryta-water*, *lime-water*, *basic acetate of lead*, or *nitrate of silver*, and dark red with *stannous chloride*. With solution of *alum* it forms a beautiful red lake, not acted upon by alkaline carbonates.

The indigo obtained from the flowers of *Tankervillia cantonensis* contains a red substance, soluble in alcohol, but insoluble in water and in ether.

For further details respecting these indigo-reds, which are probably identical in the main with Schunck's indirubin (p. 268). See *Gmelin's Handbook*, xiii. 45.

INDIGO-SULPHURIC ACIDS. When indigo-blue is macerated in fuming sulphuric acid, heat is evolved, and a deep-blue solution is formed, called *sulphate of indigo*, *Saxony* or *composition-blue*, containing sulphindigotic acid, $C^8H^5NO.SO^3$. The liquid has a deep-blue colour, and may be diluted with water without becoming turbid; if, however, the sulphuric acid is not in excess, there generally remains a purple powder, consisting of sulphophœnicic acid, $2C^8H^5NO.SO^3$, insoluble in dilute acids, but soluble, with blue colour, in pure water. According to Berzelius, there is also formed a third acid, called hyposulphindigotic acid, which has not been analysed. The indigo-blue cannot be recovered from these acids by any known methods. Their solution loses its colour after a while, and is instantly turned yellow by a small quantity of nitric acid: this reaction is used in qualitative analysis for the detection of nitric acid.

Hyposulphindigotic acid. *Hyposulphocærulic acid.* To isolate this acid, the alcoholic solution of its ammonium-salt, obtained in the manner presently to be described (see SULPHINDIGOTIC ACID), is mixed with an alcoholic solution of acetate of lead; the whole is completely precipitated by addition of a little ammonia, and the precipitate is suspended in water and decomposed by sulphydric acid. A yellow liquid is then obtained, which, on exposure to the air, becomes blue, and is converted into hyposulphindigotic acid. By evaporating this solution, the acid is obtained as an amorphous mass, which becomes moist in contact with the air, dissolves readily in water, and reacts like sulphindigotic acid with sulphydric acid, zinc, iron, and charcoal.

The hyposulphindigotates resemble the sulphindigotates in many respects, but are distinguished by their solubility in alcohol of 84 per cent. When gently heated, they give off sulphurous anhydride without changing colour; at a higher temperature, they turn green and yield a sublimate of sulphite of ammonium.

The *ammonium-*, *potassium-* and *sodium-salts* are obtained by steeping wool dyed with sulphate of indigo in solutions of the corresponding alkaline carbonates, evaporating the resulting solutions to dryness, and exhausting the residues with alcohol, which takes up only the hyposulphindigotates.

The *aluminium-salt* resembles the corresponding salt of sulphindigotic acid.

The *barium-salt* is obtained by precipitating the potassium-salt with carbonate of barium, in dark-blue flocks, very soluble in pure water; the solution, when evaporated, deposits films having a coppery lustre.

The *calcium-* and *magnesium-salts* are very soluble in water and in alcohol.

The *lead-salt* is obtained by precipitating an alcoholic solution of the ammonium-salt with alcoholic acetate of lead. It is a blue powder, which dissolves slowly but completely in water: it is sparingly soluble in alcohol, and has an astringent taste.

Sulphindigotic Acid. $C^8H^5NO.SO^3$. *Sulphate of indigo*, *Soluble blue indigo*, *Sulphindylic acid*, *Sulphocærulic acid.*—Indigo may be dissolved in strong (monohydrated) sulphuric acid (SH^2O^4), as well as in the fuming acid (which contains sulphuric anhydride in solution), but it requires 15 pts. of the former, and only 6 pts. of the latter; moreover, the solution in common sulphuric acid requires the aid of heat, which gives rise to the formation of sulphurous acid; it may, however, be facilitated by triturating the indigo with pounded glass so as to divide the particles.

The acid solution is diluted with from 30 to 50 times its bulk of water; the liquid is filtered from the precipitated sulphophœnicic acid; the filtrate is digested at a gentle heat with wool or woollen stuff (previously prepared by washing, first with soap and then with water containing 1 per cent. carbonate of sodium, and finally with pure water), until no more colouring matter is taken up, the excess of sulphuric acid remaining in solution. The wool, dyed blue by sulphindigotic and hyposulphindigotic acids, is washed with water till the latter no longer becomes acid, and digested

Ferric and *cupric salts* instantly turn the solution blue, and are converted into salts of the lower oxides. The solution reduced by *stannous chloride* deposits, on exposure to the air, a white powder, which is a mixture of stannic oxide and a product of decomposition which becomes green on exposure to the air.

Sulphindigotates, when heated, give off water without melting. When strongly heated, they decompose, evolving free ammonia, carbonate of ammonium, cyanide of ammonium, a trace of volatile oil, and afterwards of carbonic anhydride, whilst a residue of metallic sulphide is left.

Sulphindigotate of Ammonium is prepared by the process described on page 258 (Berzelius); or by precipitating sulphindigotic acid, which should not be too dilute, with ammonia or a salt of ammonia (Crum). It reacts similarly to the potassium-salt. It melts when heated and swells up, but is not decomposed, even by a pretty strong heat, and although it assumes a charred appearance, still dissolves completely in water, forming a blue solution. When more strongly heated, it yields a sublimate of sulphite of ammonium (Berzelius.) It dissolves in from 40 to 50 parts of cold water, and in a much smaller quantity of hot water (Crum), and is precipitated from the solution by the alkaline sulphates and some other salts, but much less completely than the potassium-salt. It is not soluble in alcohol. (Crum, Berzelius.)

Sulphindigotate of Aluminium is readily soluble in water, and dries up like the other sulphindigotates on the evaporation of the solution. Sulphindigotate of potassium, mixed with a salt of aluminium and a little ammonia, throws down a dark blue pulverulent basic salt, becoming blackish-blue when dried. It gives up all its acid to an excess of alkali. (Berzelius.)

Sulphindigotate of Barium is precipitated in dark blue flakes, on mixing the potassium-salt with chloride of barium (Crum, Berzelius). It dissolves slightly in cold water with a bluish colour; more abundantly in hot water, imparting to it a dark colour. Owing to the great affinity of baryta for sulphindigotic acid, this salt is formed when hyposulphindigotate of potassium is mixed, first with sulphuric acid, and then with chloride of barium; an excess of sulphate of barium is, however, necessary to the reaction, and hence the precipitate has a paler colour. Sulphate of barium already precipitated likewise forms with hyposulphindigotate of potassium, a small quantity of sulphindigotate, and becomes pale blue.

Sulphindigotate of Calcium is soluble in water, but insoluble in alcohol, which precipitates it in blue flocks.

Sulphindigotate of Lead is precipitated in dark blue flocks, slightly soluble in water on mixing neutral acetate of lead with sulphindigotate of potassium. Basic acetate of lead forms a light blue precipitate, which becomes darker when dry.

Sulphindigotate of Magnesium is very soluble in water, and is not precipitated by an excess of sulphate of magnesium.

Sulphindigotate of Potassium, $C^8H^4KNO.SO^3$. This salt is obtained: 1. By steeping wool dyed blue with sulphate of indigo, in a solution of carbonate of potassium, evaporating the solution, and treating the residue with alcohol, which extracts hyposulphindigotate of potassium. The residue is then treated with acetic acid and alcohol to remove the excess of carbonate (Berzelius).—2. Indigo-blue is treated with excess of sulphuric acid; and after the sulphophœnicic acid has been removed by filtration, the blue liquid is saturated with acetate of potassium; the resulting blue precipitate is thrown on a filter, and washed with acetate of potassium till the liquid which runs through begins to turn blue; the salt is then washed with alcohol to remove the acetate. (Dumas.)

Sulphindigotate of potassium in the dry state, forms a copper-coloured mass, yielding a blue powder; blue also by transmitted light. It rapidly absorbs moisture from the air.

When heated it does not melt or evolve any purple vapours; it is difficult to incinerate. According to Berzelius, it forms sulphopurpurate of potassium when heated with lime-water out of contact with the air; in presence of air, it forms salts of sulphoflavic, sulphofulvic, and sulphorufic acids.

Sulphindigotate of potassium dissolves in 140 parts of cold water, and in a much smaller quantity of boiling water, a portion separating out on cooling. The solution is of a dark blue colour, transparent only when viewed in thin layers; when held up before the light of the sun or of a candle, it appears scarlet. 1 part of the salt imparts a blue colour to 500,000 parts of water. Water containing 1 per cent. of acetate of potassium does not dissolve the salt in the cold; on heating, a portion dissolves and separates out in blackish flakes on cooling. It is readily dissolved by sulphuric acid, but is not soluble in concentrated hydrochloric acid (Crum); or in alcohol of specific gravity 0·80. (Berzelius.)

If an aqueous solution of sulphindigotate of potassium is mixed with a barium- or

Digitized by Google

calcium-salt and carbonate or phosphate of sodium added, carbonate and phosphate of barium and carbonate of calcium are precipitated of a light blue colour, and phosphate of calcium of a deep blue colour. When the solution of sulphindigotate of potassium is mixed with acetate of lead and a solution of tannic acid, the precipitate of tannate of lead carries down all the colouring matter with it.

Sulphindigotate of potassium occurs in commerce as paste or dry powder, known as precipitated indigo, indigo-carmine, soluble indigo, or solid blue. It is used for dyeing linen of an azure-blue colour, and for producing very pure blue colours on wool.

Sulphindigotate of Sodium, also called indigo-carmine, resembles the potassium-salt, and is used for similar porposes, but is more soluble in saline solutions.

Sulphophœnicic acid, $2C^8H^5NO.SO^3$. *Indigo-purple, Phœnicin, Sulphopurpuric acid.*—This acid is formed when sulphuric acid is allowed to act upon indigo for a short time, or not in excess. To prepare it 1 pt. of indigo-blue is mixed with from 8 to 10 pts. of strong sulphuric acid, and kept for three days at a temperature of 50° or 60°; the solution is then diluted with water, and the precipitate of sulphophœnicic acid is filtered, washed with dilute hydrochloric acid, and dried in an oil-bath at 80°—100° (Dumas). Or powdered indigo is purified by boiling with dilute sulphuric acid, and then shaken up with from 7 to 8 pts. of strong sulphuric acid till the mixture becomes olive-green. The whole is then diluted with a very large quantity of water, and the precipitate of sulphophœnicic acid is collected on a filter and washed with water, which becomes more deeply blue in proportion as the sulphuric acid is removed. The last filtrates are evaporated to dryness. (Crum.)

As the extraction of the sulphophœnicic acid on the filter according to (1) is a very slow process, and when the greater part of the indigo-blue is converted into sulphophœnicic acid by the prolonged action of the sulphuric acid, water will no longer pass through the filter, the following method may be employed, which yields a more abundant, though less pure product. 1 pt. of powdered indigo is shaken in a flask with 10 pts. of strong sulphuric acid, till the blue colour which the indigo had at first lost is completely restored. For this purpose, from ten to twelve hours are requisite at 7°, three hours in the heat of the sun, 20 minutes at 38°, and a few moments at 100°. A large quantity of water is added; the solution is filtered; and the precipitate is taken from the filter and washed by decantation with water containing sufficient chloride of ammonium to prevent it from dissolving the sulphophœnicic acid. The solution of chloride of ammonium is allowed to run from the filter, and the precipitate is removed and suspended in a large quantity of water. After three days, the solution is poured off, and the water is renewed as long as sulphophœnicic acid continues to dissolve. The sulphophœnicic acid is then precipitated from the decanted solutions by chloride of potassium, and the precipitate is washed on a filter with water as long as the water continues to pass through. Sulphophœnicic acid thus prepared contains a little potassium-salt and a large quantity of earthy matter; after drying, it is no longer soluble in water. (Crum.)

Häffely triturates 1 pt. of finely powdered indigo with 20 pts. of common sulphuric acid; allows the whole to stand for some time, till a drop of the solution, which is at first blue, colours water or paper violet; and then mixes the solution with a large quantity of water: the action of the sulphuric acid is promoted by heating the whole to 40°. If less sulphuric acid is used, it must be more strongly heated; if only 3 pts. of sulphuric acid are employed for 1 pt. of indigo, the latter is not completely converted into sulphophœnicic acid. If fuming sulphuric acid is used, it is not easy to discover when the reaction is ended.

Properties.—Sulphophœnicic acid forms a blue mass or a purple-red powder, soluble in water, to which it imparts a blue colour. It dissolves readily, with blue colour, in sulphuric acid, especially in the fuming acid, being at the same time gradually converted into sulphindigotic acid. With a large quantity of soda-ley, it forms a yellow solution which turns blue if immediately mixed with sulphuric acid of 66° B.; but stronger sulphuric acid added after 24 hours, produces a whitish precipitate. (Gros-Renaud, Dingl. pol. J. 129, 288.)

The *sulphophœnicates* are precipitated from the aqueous solution of the acid by the addition of other salts. When dry they are red; their aqueous solutions are blue. They dissolve very sparingly in water, but more readily in alcohol. The solutions are reduced to yellow liquids by heating with sulphydric acid, by sulphate of iron and lime, or by caustic alkalis. The reduced solutions turn blue on exposure to the air, and on the addition of other salts, the salt of sulphophœnicic acid is precipitated unchanged.

The *ammonium-salt*, when heated, evolves sulphurous anhydride together with sulphite of ammonium, and a red vapour which yields a sublimate like indigo-blue. This

Digitized by Google

sublimate is often bright green on the lowest edges, like the wing-cases of cantharides, and turns brown when burnished.

The *potassium-salt*, $C^{16}H^9KN^2O^2.SH^2O^4$(?) is obtained by adding acetate of potassium to the aqueous solution of the acid. It is then precipitated in purple flocks, which must be washed, first with acetate of potassium, then with alcohol. It dissolves in 100 pts. of water.

The *sodium-salt* is obtained in like manner.

The solution of sulphophœnicic acid, even when very dilute, is precipitated by the salts of *calcium*, *magnesium*, *aluminium*, *iron*, *tin*, and *copper*.

Products obtained by decomposition of the Indigo-sulphuric acids.

The following products of the decomposition of these acids are described by Berzelius (*Lehrbuch der Chimie*, 4th Aufl. vii. 226); but their composition is very uncertain, and they require further examination:—

1. **Sulphoflavic acid.**—This acid is formed by heating sulphoviridate of potassium with lime-water in contact with the air.—To prepare it, sulphindigotate of potassium is heated with lime-water in an open vessel, until the solution acquires a pure red colour (if the action is too prolonged, it becomes yellow; if the access of air is kept under control, it is easier to hit the right moment). Carbonic anhydride is then passed through the liquid; the filtrate evaporated to dryness, and the green, brownish-yellow residue extracted with alcohol. The yellow solution is precipitated with acetate of lead; the lemon-yellow precipitate suspended in water and decomposed by sulphydric acid; and the solution filtered from the sulphide of lead is then left to evaporate. It forms yellow arborescent masses, having a strong acid taste and reaction. It is soluble in water and in alcohol; the solution forms with acetate of lead a lemon-yellow precipitate, insoluble in water.

2. **Sulphofulvic and Sulphorufic Acids.**—These acids are formed simultaneously with sulphoflavic acid. The residue, from which the sulphoflavic acid has been extracted by alcohol, is dissolved in water, and the bright-red solution is precipitated with basic acetate of lead. The pale-red precipitate is suspended in water, and decomposed with sulphydric acid, and the filtrate is evaporated to dryness. Absolute alcohol extracts from the residue, sulphofulvic acid, which, on evaporation, is deposited as a dark yellow, transparent mass, having the consistence of an extract; it forms a lead-salt, is readily soluble in water and in alcohol. The portion insoluble in alcohol is sulphorufic acid. This latter dissolves in water with a fine red colour, and, on evaporating the water, forms a dark red, opaque, amorphous mass, which tastes acid and strongly reddens litmus. The lead-salt is readily soluble in water and in alcohol.

3. **Sulphopurpuric Acid.**—This acid is formed by the action of alkalis upon sulphoviridic acid. 1 pt. of sulphindigotate of potassium is dissolved in 50 pts. of lime-water and heated in a covered vessel, till the solution, which has gradually turned purple red, does not become green again on cooling. After the whole has been allowed to cool in the covered vessel, the excess of lime is precipitated by carbonic acid; the filtrate is evaporated to dryness; and the residue treated with alcohol, which extracts a little sulphoflavic acid. The residue is dissolved in water, the purple-red solution precipitated with acetate of lead, and the precipitate suspended in water and decomposed by sulphydric acid; the filtered solution is then evaporated to dryness.

Sulphopurpuric acid forms a brown uncrystallised mass, dissolving in water with dark purple-red colour. The potassium-salt dissolves in water and imparts to it a dark purple-red colour, like that of permanganate of potassium. The precipitate produced by mixing the aqueous solution of the acid with acetate of lead, is slightly soluble in water, with a reddish colour; insoluble in alcohol. With excess of oxide of lead, a pale red salt is formed, which is insoluble in water.

4. **Sulphoviridic Acid.**—This is the first product of decomposition in the action of alkalis upon sulphindigotic acid.

1. To an alcoholic solution of an alkaline hyposulphindigotate, hydrate of potassium is added in small portions until it becomes green, and the green precipitate is washed on a filter with a little alcohol. The precipitate is decomposed by an aqueous solution of oxalic acid, filtered, and the filtrate is freed from excess of oxalic acid by triturating it with a little carbonate of calcium: it is then filtered and evaporated to dryness.

2. When a solution of hyposulphindigotate of barium is evaporated to dryness on a water-bath, it becomes green and yields a precipitate with basic acetate of lead, but not with the neutral acetate; and if the greyish-green precipitate is decomposed by sulphydric acid and the green filtrate evaporated to dryness, sulphoviridic acid is obtained as a dry, hard, gummy mass, having a strong acid reaction.

Digitized by Google

It dissolves very readily in water, and slowly, but completely, in strong alcohol the solutions appear dark green by reflected light, and dark red by transmitted light. The aqueous solution mixed with lime-water becomes yellow in contact with the air. The *lead-salt* is somewhat soluble in water, imparting to it a greenish colour.

INDIGOTIC ACID. Syn. with NITROSALICYLIC ACID. (See SALICYLIC ACID.)

INDIGOTIN. Syn. with INDIGO-BLUE.

INDIGO-WHITE. $C^{16}H^{12}N^2O^2$. *White Indigo, reduced* or *deoxidised Indigo, Indigogen* (Gm. xiii. 93; Gerh. iii. 510).—A colourless substance, produced by the action of reducing agents on indigo-blue (pp. 251, 254), and differing from a double molecule of the latter ($C^{16}H^{10}N^2O^2$) by two atoms of hydrogen. Chevreul, who was the first to isolate it, supposed that it existed ready formed in indigoferous plants, and was converted into indigo-blue by oxidation; but Schunck has shown that this view is untenable, because indigo-white is soluble only in alkaline liquids, and the juice of plants is always acid. Moreover, if the indigo-white existed in the juice of these plants, it would be converted into indigo-blue by oxidation, on coming to the surface, which is not the case.

Preparation.—Commercial indigo, purified by boiling with hydrochloric acid, next with strong potash, and afterwards with alcohol, is mixed with freshly prepared hydrate of calcium (2 parts of quick-lime to 1 of indigo) and placed in a closed vessel with 150 parts of boiling water, after which sulphate of iron equal to one-third the weight of the indigo is added, and after the vessel has been closed, the whole is carefully shaken. After two days, the solution is decanted by means of a siphon into flasks filled with carbonic anhydride, and when the flasks are nearly full, they are completely filled with boiling dilute hydrochloric acid, corked up, and placed in a vessel containing cold water. The air is thus prevented from obtaining access to the indigo-white, which separates out in white crystalline flakes. After the indigo-white has settled down, the solution is drawn off with a wide siphon, and the deposit is thrown upon a filter, which is covered with a bell-jar, into which a stream of hydrogen or carbonic anhydride is passed. The filter is washed with cold water, which has been well boiled and then corked up. Indigo-white is very easy to wash, and if the deposit is allowed to stand for several days, it becomes so consistent that it may be washed in the air without becoming deeply coloured. After the contents of the filter have been washed, they are spread, while still moist, upon a glass plate and dried in a vacuum. When the indigo-white is dry, carbonic anhydride is allowed to flow into the receiver of the air-pump, in order that the pores of the dry mass may become filled with the gas (Berzelius, Dumas).—2. Three pts. of indigo-blue which have been purified by boiling, are digested for 24 hours with 5 pts. of hydrate of calcium, 4 pts. of sulphate of iron, and 120 pts. of water, in a closed flask filled with hydrogen, and the whole is frequently shaken till the deposit assumes a greenish-yellow and the solution a reddish-yellow colour. The lime is precipitated from the latter with carbonate of potassium, and the clear solution is decanted by means of a siphon filled with hydrogen, into a flask containing a mixture of hydrochloric acid and sulphite of ammonium. The thick white precipitate which is thus formed is filtered out of contact with the air, washed with water containing a little sulphite of ammonium, and dried at 100° in a stream of hydrogen. (Liebig.)

Properties.—Indigo-white thus prepared forms a coherent greyish-white mass having a faint silky lustre; if absolutely pure, it would probably be quite white. It is tasteless, inodorous, and does not change the colour of litmus. It is perfectly insoluble in *water*, and in such *acids* as do not decompose it, but dissolves in aqueous *alkalis*, in *alcohol*, and in *ether*, forming yellow solutions, which, when exposed to the air, turn yellow and deposit indigo-blue.

Decompositions.—1. When indigo-white is heated in a vacuum, a little water is evolved, a small quantity of indigo-blue sublimes, and a large carbonaceous residue is left (Berzelius).—2. When exposed to the *air*, and in contact with various *oxygen-compounds*, it takes up oxygen and is converted into indigo-blue. Freshly precipitated indigo-white turns blue immediately when shaken with water containing air, even if a free acid is present. After washing, and while still moist, it becomes purple through its entire mass on exposure to the air, unless it is rapidly dried. When dry, it requires several days' exposure to the air, to oxidise it completely, first becoming bright blue, and then dark blue through the entire mass. It cannot be preserved in sealed tubes, since the air contained in its pores is sufficient for its conversion into indigo-blue. Dry indigo-white exposed to the air at a gradually increasing temperature, suddenly becomes dark purple. When a *cupric salt* is added to an alkaline solution of indigo-white, a salt of the alkali, together with indigo-blue and cuprous oxide, are formed; the latter, on the addition of sulphuric acid, is decomposed into cuprous oxide, which dissolves, and a residue of metal.—3. Indigo-white precipitated from an alkaline

Digitized by Google

solution by *nitric acid*, is turned blue by a slight excess of the acid, and then more completely decomposed (Berzelius). It dissolves instantly in *sulphuric acid*, and imparts to it a dark purple colour, which passes to blue on dilution. According to Berzelius, the indigo-white is oxidised, and part of the sulphuric acid converted into hyposulphuric acid.

Metallic Derivatives of Indigo-white.—Indigo-white dissolves readily in all aqueous *alkalis* and *alkaline earths*, also in the aqueous carbonates of ammonium, potassium, and sodium, and, according to Liebig, without depriving them of their alkaline reaction. The cold solutions are pure yellow, the warm and highly concentrated solutions brownish-yellow. When exposed to the air, they immediately deposit indigo-blue.

Indigo-white forms with *lime* a neutral compound, readily soluble in water, and a basic compound which is almost insoluble; this latter is precipitated when the solution of the more neutral body is digested with hydrate of calcium, or when indigo is digested with water, sulphate of iron, and excess of lime. The precipitate of gypsum and hydrated sesquioxide of iron, which is formed at the same time, may be readily suspended in water and separated by levigation. The basic compound is of a lemon-yellow colour, and very slightly soluble in water, to which it imparts a yellow colour. On exposure to the air, it first turns green, and then bright blue. (Berzelius.)

The alkaline solutions of indigo-white are precipitated by the salts of the *earth-metals* and *heavy metals*, yielding white precipitates, which turn blue in the air more quickly than indigo-white itself. The *magnesium-compound*, being slightly soluble, is partly thrown down as a white precipitate, and partly remains dissolved in the aqueous solution, to which it imparts a yellow colour; it turns blue on exposure to the air. The *aluminium-compound* is white, but rapidly turns blue on the filter; if it be then dried, it forms a dark blue crystalline powder which sparkles in sunshine; indigo-blue may be very readily sublimed from it, and a grey earthy residue then remains. (Berzelius.)

The *manganous compound* is dirty-green, and does not yield any sublimate of indigo-blue when dried in the air and heated. The *zinc-compound* is white, but rapidly turns blue on exposure to the air, and then yields a sublimate of indigo-blue when heated. The *lead-compound* is white and slightly crystalline, turns rapidly blue on exposure to the air, and if then heated, detonates slightly, and yields reduced lead. The *ferrous compound* is white, but quickly turns blue on exposure to the air; if it be *then* heated, it does not yield any sublimate of indigo-blue. The *cobalt-compound* is grass-green, and after drying in the air, does not yield any sublimate of indigo-blue when heated. Nitrate of *silver* produces with an aqueous solution of the potassium-compound a precipitate which is at first transparent brown, and then becomes black; it is not acted upon by the air, but when heated, produces a gentle explosion and yields a sublimate of indigo-blue and a residue of metallic silver. (Berzelius.)

INDIGO-YELLOW. A substance produced by heating hyposulphindigotate of calcium with lime-water, in contact with the air. It is a transparent yellow mass, with neutral reaction; swells up when heated, emitting an odour like that of burnt animal matter, and is slowly converted into a combustible cinder. It dissolves in water and in alcohol, forming yellow solutions. The aqueous solution is precipitated incompletely by neutral acetate of lead, completely by the basic acetate.

INDIHUMIN. A product of the decomposition of indican (p. 248) perhaps identical with indigo-brown. It is obtained but sparingly, and not on all occasions. It is a brown powder, containing 62·86 per cent. carbon, 4·71 hydrogen, 7·19 nitrogen, and 25·24 oxygen, agreeing nearly with the formula $C^{16}H^9NO^3$. It burns without melting when heated, is insoluble in water and in alcohol, but dissolves in aqueous alkalis, forming a brown liquid, from which it is precipitated by acids. It dissolves in boiling nitric acid, forming a yellow solution, which, on evaporation, leaves an orange-yellow residue.

INDIN. $C^{16}H^{10}N^2O^2$. (Laurent, Ann. Ch. Phys. [3] iii. 471.)—A compound, probably containing the elements of two molecules of indigo-blue, produced by the action of potash on isatyde, sulphisatyde, or disulphisatyde by heating isatan or isatyde:—

$$\underset{\text{Isatan.}}{C^{16}H^{12}N^2O^2} = \underset{\text{Indin.}}{C^{16}H^{10}N^2O^2} + H^2O.$$

$$\underset{\text{Isatyde.}}{2C^{16}H^{12}N^2O^4} = \underset{\text{Indin.}}{C^{16}H^{10}N^2O^2} + \underset{\text{Isatin.}}{2C^8H^5NO^2} + 2H^2O.$$

$$\underset{\text{Isatyde.}}{2C^{16}H^{12}N^2O^4} + 3KHO = \underset{\text{Indin-potassium.}}{C^{16}H^9KN^2O^2} + \underset{\text{Isatate of potassium.}}{2C^8H^6KNO^3} + 3H^2O.$$

$$\underset{\text{Sulphisatyde.}}{2C^{16}H^{12}N^2SO^3} + 3KHO = C^{16}H^9KN^2O^2 + 2C^8H^6KNO^3 + H^2O + 2H^2S.$$

$$\underset{\text{Disulphisatyde.}}{2C^{16}H^{12}N^2S^2O^2} + 4KHO = C^{16}H^9KN^2O^2 + 2C^8H^6KNO^3 + KHS + 3H^2S.$$

decomposed chlorisatyde by boiling alcohol. Or, chlorisatyde is dissolved in warm potash, and allowed to cool: the mother-liquor is poured off from the deposit of chlorisatate of potassium, and mixed with acetic acid, which precipitates yellow chlorisatic acid. On subsequently heating the filtrate with hydrochloric acid, it assumes a deep orange colour, and deposits violet flakes of chlorindin, which are filtered from the hot solution.

Chlorindin forms a dirty violet powder, insoluble in water, hydrochloric acid, and *alcohol*. It dissolves in *potash*, forming a yellowish solution, with which hydrochloric acid gives a yellow precipitate, soluble with yellow colour in water.

Tetrachlorindin. $C^{16}H^{8}Cl^{4}N^{2}O^{2}$. (Erdmann, *loc. cit.*)—Produced from chlorisatyde by the action of heat below 200°, or by the action of potash. It resembles chlorindin.

Hydrindin. $C^{32}H^{22}N^{4}O^{5}$? (Laurent, Ann. Ch. Phys. [3] iii. 475.)—A compound produced by the action of alcoholic potash upon indin, isatin, isatyde, sulphisatyde, or disulphisatyde.

Preparation.—1. Indin moistened with alcohol is warmed with strong potash-ley till the solution, which is at first black, has become colourless, and the crystals of hydrindin-potassium, which separate out on cooling, are completely freed from potash by water.—2. When isatyde is treated with potash and a little alcohol, a beautiful rose-coloured solution is formed, which, when mixed with hydrochloric acid, and gently evaporated, becomes yellow, and deposits on cooling a mixture of isatin and hydrindin, from which the isatin is extracted by treating with a little boiling alcohol. —3. Sulphisatyde dissolves completely in gently heated potash, and on cooling, the potassium-compound of hydrindin sometimes separates out in beautiful small, pale-yellow crystals; sometimes, however, the solution solidifies into a mass of needles having a silky lustre. The whole is mixed with a large quantity of water, and the crystals are washed on a filter till all the potash is extracted. The filtrate mixed with hydrochloric acid still deposits a small quantity of hydrindin, together with a substance which is perhaps indin.

Hydrindin forms a white or pale-yellow powder, insoluble in *water*, slightly soluble in boiling *alcohol*, and separating from the solution on cooling, in small rhombic or six-sided needles.

Hydrindin carefully heated above 300°, turns violet-brown and gives off 2 at. water; the residue behaves with alcoholic potash like indin.—With boiling nitric acid it forms a violet powder similar to nitrindin.

Hydrindin contains, according to the mean of Laurent's analyses, 69·80 per cent. C, 4·85 H, and 10·70 N. The formula, $C^{32}H^{22}N^{4}O^{5}$, deduced therefrom by Laurent, which represents hydrindin as composed of 2 at. indin + $H^{2}O$, requires only 4·0 per cent. H, which is much below the analytical number. Gerhardt suggested the formula $C^{32}H^{22}N^{4}O^{4}.H^{2}O$, which requires 70·59 per cent. C, 4·41 H, and 10·29 N, and represents hydrindin as a hydrate of a double molecule of indin + 2 at. H. The formation of hydrindin by the action of potash on indin, &c. is more favourable to Laurent's than to Gerhardt's view, provided hydrindin is the sole product of the reaction; but in reality other products are formed at the same time, so that the formation of the more highly hydrogenised compound, hydrindin, may perhaps be compensated by that of one or more compounds containing a larger proportion of oxygen. The organic molecule, $C^{16}H^{12}N^{2}O$, associated with the elements of sulphuric acid in Schlieper's hydrindinsulphuric acid (p. 267) differs from indin by the substitution of 2 at. H for 1 at. O; but as the mode of formation of this molecule is altogether different from that of Laurent's hydrindin, it is probable that the two have little more in common than the name.

Hydrindin-potassium. $C^{32}H^{21}KN^{4}O^{5}.3H^{2}O$? When hydrindin is dissolved in warm aqueous potash, this salt separates out in short, brilliant, pale-yellow prisms or silky needles, containing, according to Laurent's analysis, 60·0 per cent. C, 4·3 H, 5·6 K, and 9·0 water of crystallisation; these numbers agree better with Laurent's formula above given, which requires 60·54 per cent. C, 4·27 H, and 6·18 K, than with that which corresponds to Gerhardt's formula of hydrindin, viz. $C^{32}H^{21}KN^{4}O^{4}.3H^{2}O$ which requires 62·11 C, 4·37 H and 6·34 K. The salt is decomposed by washing with water, leaving nothing but hydrindin.

Nitrindin. $C^{16}H^{8}N^{4}O^{6} = C^{16}H^{8}(NO^{2})^{2}N^{2}O^{2}$. (Laurent, Ann. Ch. Phys. [3] iii. 478.)—Produced by boiling indin or hydrindin with nitric acid. Isatyde and sulphisatyde probably also yield nitrindin when boiled with nitric acid.

It is a bright violet powder, insoluble in water, very slightly soluble in alcohol and ether.

It decomposes rather quickly when heated in closed vessels, and leaves a residue of bulky charcoal, which glows even out of contact with the air. It is gradually decomposed by boiling *nitric acid*. It dissolves in *potash*, forming a deep brown solution,

Digitized by Google

from which hydrochloric acid throws down sometimes undecomposed indin, and sometimes yellow flakes, especially if the solution has been boiled. With *sulphite of ammonium* it behaves like indin. Ammonia does not act upon it.

INDINSULPHURIC ACID. $C^{16}H^{12}N^2S^2O^9 = (C^{16}H^{10}N^2O^2.SO^3).SH^2O^4$. (G. and A. Schlieper, Ann. Ch. Pharm. cxx. 24.)—An acid produced by the oxidation of hydrindinsulphuric acid (see below). The transformation may be effected by heating hydrindinsulphuric acid with a few drops of nitric acid, or by treating it with an alkaline of solution of ferricyanide of potassium or hypochlorite of sodium. The hydrindinsulphates are also converted into indinsulphates by exposure to the air, especially in alkaline solution, or by heating them with nitric or nitromuriatic acid. The mother-liquor obtained in the preparation of hydrindinsulphate of barium, treated with hot nitric acid, yields large quantities of the indinsulphate. The free acid may be obtained in the crystalline form by decomposing the barium-salt with sulphuric acid, and evaporating the filtrate. It has a red colour, is easily soluble in *water*, sparingly in *alcohol*, and is precipitated from the alcoholic solution by *ether*, in red flocks. The aqueous solution dyes silk and wool scarlet. Its colour is altered by *alkalis*, probably in consequence of a change analogous to the conversion of isatin into isatic acid. By *sulphydric acid* it is reduced to hydrindin-sulphuric acid:

$$C^{16}H^{12}N^2S^2O^9 + 2H^2S = C^{16}H^{14}N^2S^2O^8 + S^2 + H^2O.$$

Indinsulphuric acid is dibasic, and appears to form soluble salts with most bases. The salts when heated yield a crystalline sublimate of a fine red colour.

The *barium-salt*, $C^{16}H^{10}Ba''N^2S^2O^9.2H^2O$, is obtained, by drenching the hydrindinsulphate with dilute ammonia, exposing it to the air, and stirring frequently, as a finely crystalline powder of a fiery carmine-red colour; or, by heating the mother-liquor of the hydrindinsulphate with nitric acid, as a light powder consisting of slender dark-red, brown needles. It is moderately soluble in pure water, insoluble in aqueous chloride of barium, alcohol, and cold hydrochloric acid and nitric acids. At 100° it gives off 6·45 per cent. water (calc. 2 at. = 5·89), and the dried salt yields by analysis 33·64 per cent. carbon, 2·02 hydrogen, and 26·27 to 26·74 baryta, the formula requiring 33·39 C, 1·74 H, and 26·60 BaO.

The *potassium-salt*, $C^{16}H^{10}K^2N^2S^2O^9.5H^2O$, is obtained, by oxidising the solution of the hydrindinsulphate, by exposure to the air, or by means of ferricyanide of potassium, as a bulky carmine-coloured precipitate, perfectly insoluble in liquids containing potash. A hot solution of indinsulphuric acid mixed with excess of a potassium-salt, the chloride for example, deposits the indinsulphate on cooling in interlaced needles of a dark-red colour and almost metallic lustre, and so bulky that they nearly fill the liquid. The air-dried salt heated to 100° gave off, on the average, 14·24 and 14·34 per cent. water (calc. 5 at. = 14·85), and the remaining anhydrous salt gave by analysis 18·09 and 18·21 per cent. K^2O, the formula requiring 18·21 per cent.

The *silver-salt*, $C^{16}H^{10}Ag^2N^2S^2O^9$, is obtained by mixing a solution of the acid with excess of nitrate of silver, in small brown bulky needles yielding (at 100°) by analysis 29·39 per cent. C, 1·58 H, and 32·76 Ag; calc. 29·36 C, 1·53 H, and 33·02 Ag.

Hydrindinsulphuric acid. $C^{16}H^{14}N^2S^2O^8 = (C^{16}H^{12}N^2O.SO^3).SH^2O^4$. (G. and A. Schlieper, Ann. Ch. Pharm. cxx. 20.)—This acid, which may be derived from indinsulphuric acid by the substitution of 2 at. H for 1 at. O,* is produced by the action of sulphydric acid or sulphide of ammonium on indinsulphuric, or isatinsulphuric acid; also of zinc and hydrochloric or sulphuric acid on the latter, but not by the action of hydriodic acid.

Preparation.—A moderately concentrated solution of isatinsulphuric acid (1 pt. of the acid to 5 or 6 pts. water) is slightly supersaturated with ammonia, then mixed with half its bulk of sulphide of ammonium, and heated to boiling, the liquid then becoming brown from dissolved sulphur, and smelling strongly of ammonia. More sulphide of ammonium is then gradually added to the boiling liquid, till it smells permanently of sulphydric acid; and the boiling is continued (in a flask, to prevent oxidation) as long as a trace of ammonia escapes. The neutral pale-red solution filtered from the separated sulphur consists almost wholly of hydrindinsulphate of ammonium, which may be converted into the barium-salt by precipitation with chloride of barium, and from this the acid is obtained by decomposition with sulphuric acid.

Hydrindinsulphuric acid is obtained, by evaporation of its aqueous solution, as a colourless radio-crystalline mass, which becomes reddish when exposed to the air. It has a very sour taste, dissolves easily in *water*, less easily in *alcohol*, and is insoluble in *ether*.

The acid is dibasic; its salts are almost all soluble, and are easily converted into indinsulphates by oxidation, especially in alkaline solutions.

* In the original memoir (p. 31), the two acids are said to be related to one another in the same manner as indigo-white and indigo-blue; but this statement is inconsistent with the formulæ.

Digitized by Google

The *barium-salt*, $C^{16}H^{12}Ba''N^2S^2O^8.4H^2O$ (air-dried), is a light crystalline powder consisting of white shining scales. At 100° it gives off 11·68 per cent. water (calc. 11·37 per cent.), and the anhydrous salt yields by analysis 26·96 and 26·87 per cent. Ba^2O, the formula requiring 27·27 per cent.

Leucindin-sulphuric acid. $C^{16}H^{18}N^2S^2O^{10}$. (G. and A. Schlieper, Ann. Ch. Pharm. cxx. 33.)—This acid, which differs from the last by the elements of one molecule of water, is also produced by the action of sulphide of ammonium on isatinsulphuric acid. If in the process above described, the liquid, after filtration from the sulphur, be immediately mixed with excess of caustic baryta, instead of being evaporated, the whole of the ammonia then expelled by boiling, the excess of baryta removed by carbonic acid, and the clear yellowish solution strongly concentrated by evaporation, it deposits, after standing for a few days, white crystalline crusts of leucindin-sulphate of barium, which when recrystallised, forms hard, colourless, shining crystals containing $C^{16}H^{16}Ba^2S^2O^{10}$, with probably 5 at. water. They gave off 11·65 per cent. water at 100°, and 14·3 per cent. at 120° (mean 12·97); by calculation 5 at. = 13·1. The anhydrous salt gave by analysis (mean) 28·10 per cent. C, 3·85 H, and 22·14 Ba^2O; calculation 27·94 C, 3·78 H, and 22·27 Ba^2O.

By decomposing the barium-salt with sulphuric acid, and evaporating the filtrate, leucindin-sulphuric acid is obtained as a white crystalline mass, having a very sour taste, easily soluble in water, sparingly in alcohol. Its alkaline solutions are not reddened either by exposure to the air, or by treatment with oxidising agents. The solution of the barium-salt is not precipitated by nitrate of silver; but on adding ammonia, a white flocculent precipitate is formed, which turns brown when warmed; acetate of lead forms a red precipitate. The barium-salt evaporated down with hydrochloric or sulphuric acid, is converted into indinsulphate of barium; it is not altered by heating with potash.

INDIRETIN. $C^{18}H^{17}NO^5$. (Schunck, Phil. Mag. [4] xv. 29, 117.)—A compound, produced, together with indihumin, indirubin, and other products, by the action of dilute sulphuric acid upon indican (p. 248). It is a dark-brown shining resin, which at 100°–190°, contains on the average 66·04 per cent. C, 5·57 H, 3·83 N, and 24·56 O (calc. 66·05 C, 5·19 H, 4·28 N, and 24·48 O).—When *heated* on platinum foil, it melts, burns with a yellow, smoky flame, and leaves charcoal. By *dry distillation* it gives off strong-smelling vapours, and yields an oily distillate. It dissolves in *oil of vitriol* with brown colour, and chars when heated. With boiling *nitric acid*, it forms resin, and picric acid.—It dissolves easily in aqueous *alkalis*, and with brown colour in *ammonia*, being precipitated therefrom by *barium*, *calcium*, and *silver-salts*. It is precipitated from the alcoholic solution by *neutral acetate* of *lead*, and partially by *cupric acetate*.

INDIRUBIN. C^8H^5NO. (Schunck, *loc. cit.*)—A compound, isomeric with indigo-blue (p. 249), and perhaps identical with indigo-red (p. 257), obtained in small quantity by decomposition of indican, more abundantly from Indian woad-leaves, by immersing them in a boiling alkaline solution of stannous chloride, the liquid then depositing indirubin on exposure to the air. The product thus obtained is purified by dissolving it in alkaline stannous chloride, and treating it, after reprecipitation, with caustic soda, acids, and water, and then recrystallised from alcohol. It forms long, purple, metallic-shining needles, which appear red by transmitted light, and when heated volatilise in red vapours and sublime. In the impure state, it is a brown-red amorphous powder. Contains 72·78 per cent. C, 10·50 N, 4·16 H, and 12·56 O, agreeing with the formula above given. It dissolves with purple colour in *strong sulphuric acid*, and is partially precipitated therefrom by water. Cold *nitric* acid dissolves it with purple colour, but on applying heat, decomposition takes place, attended with formation of resin and picric acid. It is but slightly altered by a mixture of *chromate of potassium* and dilute *sulphuric acid*, even at the boiling heat. With *chlorine* under water, it forms a blue amorphous resin soluble in alcohol. Heated with *soda-lime*, it gives off an odour of benzoin, together with alkaline vapours, which partly condense to needles. It is insoluble in aqueous alkalis, but dissolves easily on addition of *stannous chloride* or *grape-sugar*. From the yellow solution, acids throw down dirty yellow flocks, which acquire a purple colour on exposure to the air, and impart a fast purple dye to cotton-wool immersed in the liquid and afterwards exposed to the air. It is not precipitated from the alcoholic solution by ammoniacal *sugar-of-lead*. Its sulphuric acid solution imparts a fine colour to wool, cotton, and silk.

INDIUM. A metal recently discovered by F. Reich and Th. Richter (J. pr. Chem. lxxxix. 441) in the zinc-blende of Freiberg. Its spectrum is characterised by two indigo-coloured lines, one very bright and more refrangible than the blue line of strontium; the other fainter but still more refrangible, approaching the blue line of potas-

INK. Every liquor or pigment used for writing or printing is distinguished by the name of ink. Inks are of various colours, but the black and red are most in use, both for writing and printing. We shall first speak of *writing inks*, which consist either of a coloured and not too thin liquid, or a finely divided coloured precipitate suspended in a liquid.

1. Black inks.—Common black ink for writing is made by adding an infusion or decoction of nut-galls to a solution of copperas (ferrous sulphate). The infusion or decoction of the galls contains both gallotannic and gallic acids, both of which produce deep-black precipitates with ferric salts, but with ferrous salts, white precipitates which turn black by oxidation on exposure to the air. Moreover, gallic acid colours ferric salts of a much deeper black than gallotannic acid; hence it is advantageous to leave the infusion to itself for some time, either before or after mixture with the iron-salts, in order that the tannic acid contained in it may be converted into gallic acid (ii. 767, 768).

To retain the precipitate in suspension, and prevent it from forming a sediment, a certain quantity of gum is always added: the gum likewise gives a certain gloss to the ink. These are the essential ingredients of good writing ink, and any other colouring matters added, for the sake of cheapness, as substitutes for a portion of the galls, only impair its quality. Logwood is sometimes used, for the sake both of the tannin and the colouring matter which it contains.

To prevent ink from becoming mouldy, various substances are added to it, such as essential oils, finely bruised cloves, a few drops of phenic acid, and sometimes (but not advantageously) corrosive sublimate. The addition of an acid retards the conversion of the ferrous into ferric salt; the ink then remains thinner and pale while kept in the bottle, and becomes darker only as the writing dries.

The following are some of the numerous recipes for the preparation of black ink, calculated for 1,000 pts. of water:—

	a	*b*	*c*	*d*	*e*	*f*	*g*
Galls	225	187	133	125	66	62	31
Copperas	75	73	55	24	22	31	19
Gum-arabic	25	73	55	24	19	31	8

	h	*i*	*k*	*l*	*m*
Galls	50	174	50	60	42
Logwood	—	—	100	20	21
Copperas	32	87	16	20	21
Sulphate of copper	—	—	—	—	5
Gum	9	43	47	20	16
Sugar	—	—	23	1000	
Vinegar	125	135	—	—	—

Of the genuine inks (*a*—*g*), *a*, *b*, and *c* are too strong for ordinary use; *d*, *e* and *f* are perhaps the best; *g* would be somewhat too pale. The rest cannot be recommended, excepting for special purposes. Sulphate of copper deepens the colour of the precipitate, but renders it more compact and heavy, and therefore more apt to settle down. A certain quantity of sugar renders the ink more fluid, and permits the addition of a larger proportion of gum. It likewise renders the ink adhesive when dry, so that a copy of the writing may easily be taken off by laying a sheet of thin unsized paper, damped with a sponge, on the written paper, and passing lightly over it a flat iron very moderately heated: ink of this quality is called copying ink.

The so-called alizarin-inks (a mere commercial name, by no means implying that they contain the alizarin of madder) consist of common ink mixed with a little free sulphuric acid, which, like other acids, retards the oxidation of the ferrous precipitate (see IRON, OXIDES OF), so that the writing becomes black only after exposure to the air; the change being, perhaps, accelerated by the neutralisation of the sulphuric acid by the basic substances contained in the paper; the ink blackens very quickly when exposed to ammoniacal vapours. A certain quantity of sulphindigotic acid (p. 258), or its sodium-salt (indigo-carmine) is usually added, so that the ink may not appear too pale in writing. An ink of this kind may be prepared by exhausting 40 pts. by weight of nut-galls with 112 pts. water, and then adding 7 pts. copperas and ¼ pt. oxalic acid. At the same time, 1 pt. of finely pulverised indigo-blue is dissolved in 4 pts. fuming sulphuric acid; the solution after 24 hours is diluted with water, and mixed with a small quantity of carbonate of soda; the precipitate is collected, washed to remove the saline solution, then suspended in water; and this liquid is added to the former till the whole exhibits a rather deep greenish-blue colour.

Chrome ink.—Runge first suggested the preparation of ink with logwood and chromate of potassium. Such ink is more easily diluted than ordinary copperas-ink, and is not liable to turn mouldy; but on the other hand, it soon becomes viscid and

Digitized by Google

gelatinous. Runge prepares it by mixing 16 pts. by weight of solid commercial extract of logwood, with 1,000 pts. water (or a decoction of 1 pt. of logwood boiled down to 8 pts. of liquid), and adds 1 pt. of yellow chromate of potassium dissolved in water. Göbel takes 24 pts. of solid logwood extract, 1,000 pts. water, and 2 pts. yellow chromate.

Vanadium ink.—Prepared by mixing a decoction of galls with vanadate of ammonia. It is black, and flows easily, because it does not contain any precipitate; it is not attacked by dilute alkalis, but acids turn it blue. (Berzelius.)

The *black-violet Rouen ink* (*encre bleue rouenaise*) is prepared by boiling 750 pts. of logwood with 6,000 pts. water, 35 pts. alum, 31 pts. gum-arabic, and 15 pts. sugar-candy, leaving the mixture to stand for two or three days, and straining through a linen cloth.

Ink in cakes.—42 pts. of good nut-galls and 3 pts. of madder are boiled in about six times their weight of water; the filtered decoction is mixed with 5½ pts. copperas, and 2 pts. pyrolignate of iron; 1½ pts. solution of indigo (in sulphuric acid, diluted with water) is then added; the mixture is evaporated nearly to dryness at a gentle heat, and with constant stirring; and the pasty mass is then made into cakes, and thoroughly dried. This ink dissolved in 6 pts. of hot water is said to make an excellent copying ink, and in 10 or 12 pts. water, a very fine writing ink.

Ink-powder.—A solid chrome-ink may be made by triturating together to a fine powder, 100 extract of logwood, 1 pt. neutral chromate of potassium, and $\frac{1}{10}$ indigo-carmine. 1 pt. of this powder added to 32 pts. water is said to make very good ink. A mixture of 4 pts. pounded galls, 2 pts. copperas, and 1 pt. gum-arabic is also frequently sold as an ink-powder.

Copying inks.—Inks for this purpose must be rather thick, not dry too quickly, and soften when moistened again, without becoming too fluid. The following preparation is much recommended: 4 pts. by weight of logwood-extract are dissolved in a mixture of 60 pts. vinegar, and 70 pts. water, and 3 pts. copperas, 2 pts. alum, 2 pts. gum-arabic, and 4 pts. sugar are then added. This ink is at first more violet than the Rouen ink, which is also used as a copying ink.

Indelible inks.—As writing executed with ordinary ink is liable to fade in course of time, the tannate and gallate of iron being gradually decomposed, and as, moreover, it is easily effaced by the action of certain chemical reagents (oxalic acid, hydrochloric acid, chlorine), it is desirable that valuable documents should be written with an ink not liable to destruction from such agencies. Various compositions have been proposed for this purpose. Most of them consist of common ink, or some other dark-coloured liquid in which finely divided carbon (Indian ink or lamp-black) is suspended. The simplest of all is made by mixing common ink with Indian ink (p. 246) rubbed up with weak hydrochloric acid. Writing executed with such ink cannot be bleached by chlorine or destroyed by acids; but the carbon may be ultimately removed by water, even when it is as finely divided as in Indian ink, and consequently penetrates the pores of the paper to a certain extent. Ink prepared in like manner with lamp-black is easily washed away. Traill's indelible ink is prepared by steeping wheat-gluten in water for 24 to 36 hours, then dissolving it with aid of heat, in strong vinegar, of specific gravity 1·033, or in pyroligneous acid, and then rubbing it up with Indian ink or lamp-black. This ink is of a fine black colour, and cannot be obliterated by water, chlorine, or dilute acids. Kind dissolves 1 pt. honey in 14 pts. water, adds 2 pts. strong sulphuric acid, and then adds a quantity of indigo-solution sufficient to render the ink visible in writing. A hot iron is then passed over the writing, whereby not only the honey is carbonised, but likewise a portion of the paper-fibre, by the action of the free sulphuric acid. The writing cannot be effaced by any chemical reagent, and only with great difficulty by mechanical means, since the ink penetrates deeply into the paper, and the charcoal is consequently separated within the pores; the paper is, however, very much attacked.

The vanadium-ink, above described, may also be used as an indelible ink; acids merely turn it blue; chlorine destroys the black colour, but does not efface the writing, even after long washing.

Red Ink.—Red ink is usually prepared either with cochineal or with Brazil-wood. The *cochineal inks* are the brightest, but at the same time the dearest and most fugitive. The best is a solution of pure carmine in caustic ammonia; it must be preserved in well-stopped vessels. Böttger recommends 1 pt. of good carmine, 120 caustic ammonia, and 1½ pt. gum-arabic. A cheaper but less brightly coloured ink is made by drenching 12 pts. of pulverised cochineal and 4 pts. of carbonate of ammonia (or pearl-ash) with 32 pts. hot water, then digesting and pouring off the clear liquid. Addition of cream of tartar and stannic chloride renders the ink more scarlet; cream of tartar and an equal weight of alum give it a crimson tint.

Brazil-wood inks are made by boiling the wood in water, adding tin-salt (stannous chloride) or cream of tartar and alum to modify the tint, and thickening with gum-

Digitized by Google

arabic; *e.g.* 4 pts. Brazil-wood boiled in 60 pts. water, the decoction boiled 36 pts., filtered, and mixed with $\frac{1}{8}$ pt. of tin-salt and $\frac{1}{4}$ pt. gum-arabic; Brazil-wood, boiled with 2 pts. alum and 2 pts. cream of tartar in 120 pts. wa liquid concentrated to 6 pts. by weight, and mixed with 2 pts. gum-arabic a sugar.

Blue inks.—The best is made by dissolving 30 pts. pure Prussian blu blue, ii. 227) in a solution of 4 pts. oxalic acid in 1,000 pts. water. A blue ink be prepared by dissolving 4 pts. of indigo-carmine in 64 pts. water, and m with 1 pt. gum arabic; but it cannot be used with steel pens.

Yellow and green inks are sometimes, though very rarely, used. The for be made with decoction of saffron or yellow berries; the latter of solution of mixed with turmeric or gamboge; or better of indigo-carmine mixed with pi It may also be prepared from the green modification of chrome-alum, namely solving 3 pts. acid chromate of potassium in 8 pts. water, adding 1 pt. alcol sulphuric acid by drops, and heating till the liquid assumes a brownish green then diluting with 16 pts. water, adding a few more drops of sulphuric acid the liquid to stand, and adding a small quantity of gum-arabic.

Sympathetic inks.—This name is applied to inks which make characters till brought out by heat or the application of some reagent. If a weak of *galls* be used, the writing will be invisible till the paper is moistened with solution of sulphate of iron. Dilute solutions of *gold* and *silver* remain c upon the paper till exposed to the sun's light, which gives a dark colour to the and renders them visible. Most *acids*, or *saline solutions*, diluted, and used with, become visible by heating before the fire, which concentrates them, and their action on the paper. Dilute *prussiate of potash* affords blue lette wetted with solution of sulphate of iron. The solution of *cobalt* in aq when diluted, affords an ink which becomes green when held to the disappears again when suffered to cool. This ink has been used in fanciful dra trees, the green leaves of which appear when warm, and vanish again on cool the heat be continued too long after the letters appear, it renders them per If oxide of cobalt be dissolved in acetic acid, and a little nitre added, the solut exhibit a pale rose colour when heated, which disappears on cooling. A of equal parts of sulphate of copper and sal-ammoniac gives a yellow colo heated, that disappears when cold.

Sympathetic inks have been proposed as the instruments of secret corresp but they are of little use in this respect, because their properties change by rema the paper for a few days; most of them have more or less of a tinge when th dry, and none of them resist the test of heating the paper till it begi scorched.

Marking inks.—Inks for marking linen must be able to withstand the water, soap, alkaline leys and acid liquids. The best are those which contai They consist of a solution of nitrate of silver, usually coloured with sap-green, colouring matter, sometimes with lamp-black, and thickened with gum. It is prepare the part of the linen to be marked with a solution of carbonate of gum, then smooth it with a hot iron, and after writing upon it, expose it shine. The writing may be effaced by a solution of cyanide of potassium without iodine.

Roder (Polyt. Notizblatt, 1856, p. 112) prepares a marking ink by dissolvi molybdic oxide in hydrochloric acid, adding 240 pts. water, 6 pts. gum-ara 2 pts. liquorice-juice. The writing is to be dried and then moistened with so stannous chloride. Inks containing gold or platinum have also been recon for this purpose, but they are too costly for general use.

An ink for writing on *zinc plant-labels* may be made by dissolving equ acetate of copper and sal-ammoniac in distilled water. When characters are with this solution on a zinc plate, the copper is precipitated, forming deep bl durable marks.

Ink for marking *copper* and *silver* vessels may be made by boiling sul antimony in strong potash-ley, leaving the liquid to cool, and filteri separated kermes. As this liquid does not act upon iron, steel pens may be writing with it on the metal. The characters on copper and silver are black durable; on tin, lead, and zinc, less durable.

Printing ink.—All inks or paints used for letter-press, copper-plate, lith printing, &c. consist essentially of well-boiled drying oils (varnishes) mixed wi black, or other pigment, according to the colour intended to be produced. S resinous matters are sometimes added to give the boiled oil the required consi

The oil most frequently used for the preparation of the varnish is linseed oil is also used in localities where it can be had cheap; but it loses more w

Digitized by Google

boiling than linseed oil, and does not easily acquire so firm a consistence. The oil should be old and well cleared, by deposition. from particles of mucus.

Ten or twelve gallons of the oil are set over the fire in an iron pot, capable of holding at least half as much more; for the oil swells up greatly, and its boiling over into the fire would be very dangerous. When it boils, it is continually stirred with an iron ladle: and if it do not itself take fire, it is kindled with a piece of flaming paper or wood: for simple boiling, without the actual inflammation of the oil, does not communicate a sufficient degree of the drying quality required. The oil is suffered to burn for half an hour or more, and the flame being then extinguished by covering the vessel close, the boiling is afterwards continued with a gentle heat, till the oil appears of a proper consistence; in this state it is called varnish.* It is necessary to have two kinds of this varnish, a thicker and a thinner, from the greater or less boiling, to be occasionally mixed together as different purposes may require, that which answers well in hot weather being too thick in cold, and large characters not requiring so stiff an ink as small ones.

The thickest varnish, when cold, may be drawn into threads like weak glue, by which criterion the workmen judge of the due boiling, small quantities being from time to time taken out and dropped upon a tile for this purpose. It is very viscid and tenacious, like the soft resinous juices, or thick turpentine. Neither water nor alcohol dissolves it; but it mingles readily enough with fresh oil, and unites with mucilages into a mass diffusible in water in an emulsive form. The oil loses from one-tenth to one-eighth of its weight by boiling into the thick varnish.

For letter-press printing ink, the addition of soap to the varnish is indispensable, to enable the ink to be taken up clearly from the types by the moistened paper, without smearing. The soap used for the purpose is yellow resin-soap; it is cut into thin slices, well dried, rubbed to coarse powder, and incorporated by small portions at a time with the varnish, which is then once more placed over the fire, to expel any remaining moisture.

The colouring matter of black printing ink is the best lamp-black, previously calcined to free it from empyreumatic oils and resins. Its somewhat brownish colour is corrected by the addition of a little Prussian blue or indigo.

The ink used by copper-plate printers differs in the oil, which is not so much boiled as to acquire the adhesive quality. This would render it less disposed to enter the cavities of the engraving, and more difficult either to be spread or wiped off (Ure).† The black is likewise of a different kind. Instead of lamp-black, or sublimed charcoal, the Frankfort black is used, which is a residual or denser charcoal, said to be made from vine-twigs. Lamp-black is said to give a degree of toughness to the ink, which the Frankfort does not; but the goodness of the colour seems to be the leading inducement for the use of the latter.

For red, blue, and yellow printing inks, the ordinary linseed oil varnish is not very well adapted, as its brown colour impairs the brightness of the tint. A good varnish for the purpose may be made by mixing copaïba balsam (previously subjected to rapid boiling with water for several hours in an open dish, to render it more tenacious, and diminish the unpleasant odour) with $\frac{1}{20}$ to $\frac{1}{10}$ of its weight of pulverised white curd soap, then warm the mixture a little, and incorporate it with the pigment previously rubbed to fine powder with spirit of wine, and dried. For the lighter colours, it is best to mix very deep-coloured pigments with a considerable quantity of carbonate of magnesia. In that case, light-coloured linseed-oil varnish mixed with $\frac{1}{20}$ white soap may be used. A fine red is formed of vermillion mixed with $\frac{1}{10}$ carmine, and $\frac{1}{4}$ magnesia. Blue is given by ultramarine (the darkest varieties used in calico-printing) with magnesia; yellow by chromate of lead. Prussian blue mixed with chrome-yellow and a large quantity of magnesia, or ultramarine with chromate of zinc, yields a fine green. Browns are obtained with bistre and sepia.

Lithographic printing ink is made in the same way as common printing ink, but with a larger proportion of lamp-black, and without addition of soap. (See LITHOGRAPHY.)

For further details on printing inks, see *Handwörterbuch der Chemie*, vii. 388, and *Ure's Dictionary of Arts*, &c. iii. 530.

* The description of the process given in the text is taken from *Ure's Dictionary of Chemistry* (3rd ed. 1851). Mr. Savage also, in his work on the *Preparation of Printing Ink* (London, 1832) says that good varnish for printing ink cannot be made without allowing the oil to burn. The German practice appears, however, to be somewhat different; for in the *Handwörterbuch der Chemie* (Bd. vii. p. 391) it is stated that the oil should be heated only till the vapour which rises from it can be set on fire with a piece of burning paper, but will cease to burn of itself after a little while, or at least will be easily extinguished by putting on the cover; further, that if this temperature be exceeded, there is great danger of the oil getting into a state of violent combustion, which cannot be extinguished even by covering the vessel, and may occasion an enormous loss of oil.

† In the *Handwörterbuch der Chemie* (vii. 399) it is stated, on the contrary, that ink for copper-plate printing is prepared with the thickest linseed-oil varnish, which has been allowed to burn.

INOCARPIN. A red colouring matter contained in the juice of *Inocarpus edulis*, a tree growing in Tahiti. The juice which exudes from incisions in the bark of young trees, or the pericarp of green fruits, is colourless, but soon turns red on exposure to the air (the juice of old trees is red as soon as it runs out), and dries up to a red gummy mass, soluble in water and in alcohol, insoluble in ether. The aqueous solution mixed with caustic alkalis exhibits a peculiar play of colours when shaken up with air. The reddened juice contains also a yellow colouring matter called xanthocarpin. (Cuzent, J. Pharm. xxxv. 241.)

INOSIC ACID. $C^5H^8N^2O^6$ (?) (Liebig, Ann. Ch. Pharm. [3] xxxiii. 129.)—An acid found in the mother-liquor of the preparation of creatine from flesh-juice. When this mother-liquor is concentrated, then mixed with alcohol till it acquires a milky consistence, and left to itself for a few days, it deposits a crystalline mixture consisting of creatine, inosate of potassium, inosate of barium, and various substances of unknown composition. The crystals are redissolved in hot water, and chloride of barium is passed into the solution, which then, on cooling, deposits crystals of inosate of barium; and this salt, decomposed by sulphuric acid, yields inosic acid.

Inosic acid is uncrystallisable, easily soluble in water, and has a very agreeable flavour of broth. Alcohol precipitates it from its aqueous solution. It is insoluble in ether. It does not precipitate barium- or calcium-salts, but with copper-salts it forms a bluish-green precipitate, insoluble in boiling water. With lead-salts it forms a white precipitate; and with silver-salts, a white gelatinous precipitate, having the aspect of alumina, soluble in nitric acid and in ammonia.

Inosic acid, heated with peroxide of lead and a small quantity of sulphuric acid, is decomposed, and the filtered liquid contains needle-shaped crystals. The *inosates*, heated on platinum-foil, decompose, giving off an odour of roast meat.

Inosate of potassium forms elongated quadrilateral prisms, very soluble in water, insoluble in alcohol. It gives off 22·02 per cent. of water at 100°, and the dried salt contains 20·7 per cent. potash. The *sodium-salt* crystallises in small silky needles, very soluble in water; insoluble in alcohol. The *barium-salt* forms elongated quadrilateral scales, having a nacreous lustre. 3,000 pts. of water at 16° dissolve 2·5 pts. of this salt; it is insoluble in alcohol. A solution, saturated at 70°, deposits part of the salt when raised to the boiling heat. The crystals, dried at 100°, contain 24·5 to 24·8 per cent. C, 2·6 H, 11·4 N, 31·1 to 33·8 O, and 30·4 BaO; whence Liebig deduces the formula $C^5H^6Ba^2N^2O^6.\frac{1}{2}H^2O$. Gerhardt considers the composition to be more correctly represented by the formula $C^5H^7BaN^2O^6.3H^2O$. The crystals effloresce in the air, giving off 19·07 per cent. water,

Inosate of copper is nearly insoluble in water and in acetic acid; very soluble in ammonia. *Inosate of silver* is sparingly soluble in pure water, and does not blacken by exposure to light.

INOSITE. $C^6H^{12}O^6$. *Inosin. Phaseomannite.* (Scherer [1850], Ann. Ch. Pharm. lxiii. 322; lxxxi. 375.—Vohl, *ibid.* xcix. 125; ci. 50.—Cloetta, *ibid.* xcix. 289.—W. Marmé, *ibid.* cxxix. 222.)—A saccharine substance isomeric with glucose, discovered by Scherer in the muscular substance of the heart (hence its name, from ἶς, ἰνός, muscle), and since found to exist in the lungs, kidneys, liver and spleen of oxen (Cloetta), also in the brain (W. Müller); in the human kidneys and in the urine, in a case of Bright's disease: at most to the amount of 0·1 per cent. It occurs also in several plants, having been obtained from green kidney beans, the unripe fruit of *Phaseolus vulgaris* (Vohl); from the green pods and unripe seeds of the garden pea (*Pisum sativum*); the unripe fruit of the lentil (*Ervum lens*), and of the common acacia (*Robinia pseudacacia*); from the heads of the common cabbage (*Brassica oleracea*, var. *capitata*); from the herb of foxglove and from extract of digitalis; from the leaves and stems of dandelion (*Taraxacum dens leonis*), not from the flowers or roots; from the shoots of the potato; from the green herb and unripe berries of asparagus; and from two cryptogamous plants, *viz. Lactarius piperatus*, L., and *Clavaria crocea*, Pers. (Marmé.)

Preparation.—From organs of the animal body. 1. The muscle of the heart, or other organs containing inosite, is exhausted with water, as for the preparation of creatine; the phosphates are precipitated from the liquid by baryta-water; the filtrate is evaporated; and the creatine allowed to crystallise out. The mother-liquor is treated with dilute sulphuric acid to remove the dissolved baryta, and, after removal of the sulphate of barium, heated as long as volatile acids escape. It is then, in order to remove the last traces of volatile acids and of lactic acid, repeatedly shaken up with ether as long as anything is dissolved. The liquid, separated from the ether, is mixed with alcohol till a turbidity begins to appear; then, after standing for some time, it is poured off from the precipitated sulphate of potassium, and mixed with more alcohol, whereby crystals of inosite mixed with sulphate of potassium are obtained. The crystals of the former are picked out and dissolved in a small quantity of warm water, which leaves the more difficultly soluble sulphate of potassium, and are purified by

Digitized by Google

recrystallisation (Scherer).—2. The fresh-chopped tissue is covered with water, and allowed to stand for 24 hours in a cool place, with frequent stirring; the liquid is then separated, and the residue pressed; the solution is heated with a little acetic acid to separate albumin and hæmatin, then strained, evaporated on the water-bath to one tenth, precipitated with neutral acetate of lead, and filtered; and the filtrate is mixed with basic acetate of lead, whereupon inosite is thrown down in combination with oxide of lead, accompanied by uric acid, cystine, and other substances. The precipitate, after washing, is decomposed under water by sulphydric acid, and the liquid filtered from the sulphide of lead; it then sometimes deposits crystals of uric acid, and when evaporated to a small bulk on the water-bath, and mixed with alcohol till a turbidity is produced, it yields crystals of inosite (Cloetta). Acetate of lead may also be added at once to the water used for making the extract (W. Müller).—3. The liquid from which the inosite is to be separated is concentrated by evaporation, and mixed, boiling, with three or four measures of alcohol; if a large precipitate, which sticks to the bottom, is thus produced, the liquid is poured off hot; but if only a slight, not sticky precipitate is produced, the hot solution is filtered through a previously heated funnel, and left to stand for 24 hours; crystals of inosite are then deposited, and are washed with a small quantity of cold alcohol. If the precipitate caused by hot alcohol is dissolved in a small quantity of boiling water, and treated like the first solution, a further quantity of inosite is obtained. In case no inosite separates from the cooled solution, the crystallisation may be facilitated by addition of ether until a turbidity remains after shaking. (Cooper Lane, Ann. Ch. Pharm. cxvii. 118.)

From kidney beans and other vegetable organs.—The fruit cut up in the bean-mill is hung in a pressing bag for half an hour in boiling water, or in steam, whereby it becomes possible to press it; the expressed liquid is then evaporated to a syrup on a water-bath, and alcohol is added till a permanent turbidity is produced. The crystals which form are purified by repeated crystallisation from water, with help of animal charcoal. (Vohl.)

Marmé, after freeing the aqueous extracts of the plants above mentioned from everything precipitable by tannic acid and neutral acetate of lead, and decolorising them as completely as possible with milk of lime or animal charcoal, precipitated them with basic acetate of lead; mixed the filtrate with ammonia, whereby a second precipitate was obtained; decomposed both precipitates with sulphydric acid; concentrated the filtrate on the water-bath till it became turbid on addition of alcohol; then mixed it with a double volume of alcohol; warmed the liquid till it became clear; and left it to itself for several days, adding a little ether if necessary, as in Cooper Lane's method. The sulphide of lead sometimes obstinately retains small quantities of inosite, which can only be removed by boiling with water.

Properties.—Inosite is deposited from its concentrated aqueous solution in crystals containing 2 at. water, $C^6H^{12}O^6.2H^2O$. According to Vohl, the crystals are tabular, like those of gypsum; according to Scherer, they are oblique prisms, arranged for the most part in groups like cauliflower-heads; according to Cloetta, they are right rhombic prisms with angles of 138·52° and 41·8°. Specific gravity = 1·1154 at 5° (Vohl). In dry air, in vacuo over sulphuric acid, or at 100°, they become white and opaque, and give off their water, leaving anhydrous inosite, $C^6H^{12}O^6$, as a white efflorescd mass, which melts at a temperature above 210°, yielding a colourless liquid, which solidifies in the crystalline state when quickly cooled, and to an amorphous mass when cooled slowly, but does not lose weight or undergo further alteration (Scherer). Anhydrous inosite separates in white, opaque crystals from the aqueous solution cooled below 0°. (Vohl). Inosite has a pure sweet taste and no rotatory power.

Hydrated inosite dissolves in 6 pts. *water* at 19° (Vohl), in 6½ pts. at 24° (Cloetta). The concentrated solution, of specific gravity 1·0548 at 19°, is not syrupy and not subject to spontaneous decomposition. Inosite is slightly soluble in cold aqueous *alcohol*, more soluble at the boiling heat; insoluble in absolute alcohol and in *ether*.

Inosite does not combine with *chloride of sodium* or *chloride of potassium*, these salts crystallising out unaltered from its aqueous solution. The aqueous solution forms, with *basic acetate of lead*, a precipitate which appears to contain $C^6H^{12}O^6.2Pb^2O$.

Decompositions.—1. After dehydrated inosite has been melted above 210°, it swells up when more strongly *heated*, and evolves gas which burns with a pale blue flame; it is afterwards charred, and then burns with a brightly luminous flame, leaving an easily combustible cinder (Scherer). When quickly heated, it gives off vapours which excite tears and produces a smell of burnt sugar (Vohl).—2. Aqueous inosite is not affected by *ozone* (Gorup-Besanez, Ann. Ch. Pharm. cx. 103).—3. The solution of inosite in dilute *nitric acid* does not give off nitrous acid till moderately concentrated; after evaporation to dryness, it contains oxalic acid. The aqueous solution of the residue, freed from oxalic acid by carbonate of calcium, deposits on standing magnificent purple-red

Digitized by Google

flocks, soluble in dilute acids and precipitable without alteration by ammonia (Vohl). When aqueous inosite is evaporated nearly to dryness with nitric acid, and the residue is moistened with ammonia and a small quantity of solution of chloride of calcium, and again evaporated, a rose-red substance remains. This reaction affords a delicate and characteristic test of the presence of inosite (Scherer, Vohl). Inosite dissolves without evolution of gas, in cold or boiling nitric acid of specific gravity 1·52, forming a solution whence oil of vitriol precipitates nitro-inosite (Vohl).—4. Inosite dissolves without coloration in *sulphuric acid*, either cold or at 100°; is not blackened till more strongly heated, and then evolves sulphurous anhydride (Vohl). It is not altered by boiling with dilute *acids* (Scherer, Vohl).—5. It may be boiled with concentrated *potash-ley*, or with *baryta-water*, without alteration or coloration (Scherer, Vohl).—6. The aqueous solution mixed with *cupric sulphate*, yields, on addition of potash-ley, a bluish green precipitate which quickly disappears on addition of excess of potash. No cuprous oxide separates from the solution in boiling, but a light blue precipitate falls when the liquid is left to stand for several days (Scherer). Aqueous inosite yields, when heated with *potassio-cupric tartrate*, a green solution, whence a bulky green precipitate separates, the supernatant liquid again becoming blue. After removing the precipitate, the filtrate shows the same change of colour when heated (Cloetta). According to Vohl, the change of colour which occurs on heating the deep azure-blue mixture of inosite and potassio-cupric tartrate, is not very striking, and is due, as well as the production of the precipitate, to the presence of traces of foreign substances.—7. Inosite is not capable of undergoing vinous fermentation (Scherer). In contact with *cheese*, *flesh*, or decaying *membrane*, and chalk, it undergoes lactous fermentation, carbonic, lactic, and butyric acids being formed. (Scherer, Vohl.)

Nitro-inosite. $C^6H^6N^6O^{18} = C^6H^6(NO^2)^6O^6$. *Inosine hexnitrique.* (Vohl, *loc. cit.*)—This compound is obtained by dissolving anhydrous inosite in nitric acid of specific gravity 1·52, and precipitating the solution with sulphuric acid. The product, which, according to the temperature attained by the mixture, separates either as a powder or as oil-drops which solidify to crystalline masses, is well washed with water and recrystallised from boiling alcohol. It forms rhombohedrons, often some lines in length; melts to an oil when heated, and solidifies to an amorphous mass which becomes crystalline after a few days. It is permanent in air, either dry or moist; insoluble in *water*, easily soluble in *alcohol*.

Nitro-inosite deflagrates without residue when quickly *heated*, and detonates under the hammer. It is decomposed when warmed with concentrated acids. It dissolves, with dark brown colour and evolution of ammonia, in cold or warm *potash-ley*. The alkaline solution precipitates cuprous oxide from *potassio-cupric tartrate*, and a mirror of metallic silver from *ammonio-nitrate of silver*. Nitro-inosite treated with *nitric acid*, *ammonia* and *chloride of calcium*, shows the coloration of inosite.

INSOLINIC ACID. See TEREPHTHALIC ACID.

INTESTINAL CONCRETIONS. These concretions are of rare occurrence in man and in carnivorous animals, but occur more frequently in herbivorous animals, especially in horses. They exhibit great diversity in their properties and composition, as well as in their origin. Many owe their origin to an albuminous exudate or blood-coagulum, which is retained in the intestine, and gradually solidified by resorption of the soluble portion. These stones consist mainly of coagulated fibrin mixed with calcium-salts and remains of food, and sometimes containing a foreign body as nucleus. In a concretion of this kind from the intestine of a child, Davy found 74 per cent. fibrin, 19 per cent. of other organic matters, and 7 per cent. inorganic salts.

A second kind of intestinal concretion consists chiefly of earthy salts, calcic phosphate and carbonate, ammonio-magnesic carbonate, and magnesic carbonate mixed or unmixed with remains of food; such stones often contain a foreign nucleus. They are most frequent in vegetable feeders, especially in horses, and often attain a weight of several pounds. A concretion from the cœcum of a cart-horse, analysed by F. Simon, was spherical, perfectly smooth, greyish-yellow, weighed 12½ oz., and consisted of three layers, deposited round a fragment of granite. All three layers consisted of ammonio-magnesian phosphate, with a small quantity of alkaline phosphates, but no phosphate of calcium. The middle layer exhibited a radiating structure from the centre outwards, with woody fibres interposed in like manner amongst the stony mass. In 100 pts., Simon found 81·11 ammonio-magnesian phosphate, and 1·5 per cent. alkaline phosphates.

Children examined stones from the colon of a man, which weighed from 500 to 1,000 grms., and consisted of plum-stones, surrounded by a smooth compact mass made up of alternate layers of earthy phosphates and ligneous matter.

The formation of these stones is due to the precipitation of earthy salts originally

Digitized by Google

dissolved in the food, and their subsequent agglomeration by intestinal mucus, or round a foreign body.

A third kind of intestinal concretion consists chiefly of undigested residues of food; such stones have usually a woody consistence, and are formed round a foreign body. Laugier examined a concretion of this kind from the rectum of a man; it consisted of a nucleus of bone, surrounded by interlaced vegetable fibres, from which water extracted 14 per cent. of animal matter having a fæcal odour, together with small quantities of sal ammoniac and chloride of calcium.

Another class of intestinal concretions consists of fatty matters mixed with small quantities of fibrin and calcium-salts. Lassaigne analysed a number of small concretions of this kind voided by a girl suffering from tuberculosis. They contained 74 per cent. fatty matters (for the most part free fatty acids, perhaps oleic and stearic), 21 animal matter, 4 phosphate of calcium, and 1 chloride of sodium.

Bezoar-stones (i. 584) must also be classed amongst intestinal concretions. (Handwörterbuch d. Chem. 2te Aufl. ii. [3] 374.)

INTESTINAL JUICE. The mucous secretion of the pouch-like glands of the intestinal canal (the Lieberkühnian glands of the small intestine and the follicles of the colon). When viewed by the microscope, it exhibits granulated cells and cell-nuclei, and, as commonly obtained, likewise small quantities of fat and epithelium. When filtered from these matters, it forms a tolerably clear, mucous, strongly alkaline liquid, which does not coagulate by heat, and is not precipitated by acetic acid, nor, when mixed with that acid, by chloride of barium. When mixed, however, with eight or ten times its volume of alcohol, it deposits white flocks, which dissolve easily and completely in water; the solution thus obtained is not precipitated by hydrochloric, sulphuric, or acetic acid, or by mercuric chloride, but gives precipitates with the neutral and basic acetates of lead.

The constituents of pure intestinal juice are the same as those of mucus. In 1,000 pts. of the filtered intestinal juice of a dog, Schmidt and Zander found 965·3 water, 34·7 solid matter, 9·6 pancreatic and intestinal ferments, together with insoluble salts, 16·6 biliary matters (cholic, taurocholic, and glycocholate of sodium), 6·3 taurine, 0·7 fat, 3·7 extractive matter, 0·15 potassium, 1·45 sodium, 2·11 chlorine, 0·03 phosphoric anhydride, 0·06 earthy phosphates. In the intestinal juice from the upper part of the colon of a man, Busch found from 3·8 to 7·4 per cent.; Frerichs, from 2·2 to 5·6 per cent. solid matter.

The intestinal juice converts starch very quickly into sugar, and digests albuminous substances, flesh, &c., though much more slowly than the gastric juice. (Handwörterbuch d. Chem. 2te Aufl. ii. [3] 373.)

INULIN. $C^6H^{10}O^5$. *Helenin, Alantin, Menyanthin, Dahlin, Synantherin, Sinistrin.*—A substance isomeric with, and similar in its properties to, starch, discovered by Valentin Rose in 1804. It appears to be a very widely distributed constituent of plants, and is found especially in the roots of elecampane (*Inula Helenium*), dandelion (*Taraxacum dens leonis*), chicory (*Cichorium Intybus*), feverfew (*Pyrethrum Parthenium*), and meadow saffron (*Colchicum autumnale*); in the tubers of the potato, the dahlia, and the Jerusalem artichoke (*Helianthus tuberosus*), in Lerp-manna (from *Eucalyptus dumosa*), and probably in the seeds of the sun-flower (*Helianthus annuus*), and in certain lichens, viz. *Lichen fraxineus* and *Lichen fastigiatus.*

Preparation.—a. From Elecampane-roots.—The roots are boiled with a large quantity of water, the decoction is evaporated, the extract exhausted with cold water, and the inulin which remains undissolved is washed (Gaultier, Stratingh).—Or the roots are exhausted with hot water in a percolating apparatus; the concentrated effusion is evaporated to 10° or 12° Bm. and mixed with 2 pts. alcohol; and the inulin thereby precipitated is purified by reprecipitation with alcohol from its concentrated solution, and decolorised with animal charcoal (Thibault).—The helenin mixed with inulin prepared from elecampane-roots is extracted by boiling with alcohol. (Croockwit.)

b. From Potatoes or Dahlia-tubers.—1. The pulverulent deposit which separates in the cold from the expressed juice of potatoes is dissolved in hot water, and the solution is filtered, evaporated, and left to cool, whereupon it deposits inulin (Braconnot). —2. The nearly transparent juice expressed from dahlia-tubers is left to stand for some hours, whereupon it solidifies, from separation of inulin, to a stiff paste, which is to be washed and dried (Ludwig, N. Br. Arch. 32, 163).—3. Dahlia-tubers rubbed to a pulp are washed on a hair-sieve in a thin stream of water, as long as the liquid continues to run through milky, and the inulin which separates from it on standing is collected; or in case it is slow in settling down, the turbid liquid is heated till it boils, the coagulated vegetable albumin is skimmed off, and the remaining liquid is left to cool; it then, after a few days, deposits a thick pulp easy to wash (Liebig, Ann.

Digitized by Google

Pharm. 2, 235).—4. Dahlia-tubers rubbed to a pulp are washed with cold water on a linen or woollen cloth; the residue is boiled for half-an-hour with 2 pts. water and a small quantity of chalk; the liquid is expressed; the extract, after being decolorised with animal charcoal and clarified with albumin, is evaporated till a film forms on it; and the inulin which separates on cooling is washed with cold water, and purified by solution in hot water and cooling. (Payen.)

Parnell uses peeled and washed dahlia-tubers, boils them for an hour and a half with 5 pts. of water, and purifies the inulin which separates from the evaporated extract by precipitating its aqueous solution with alcohol. Croockwit purifies the inulin thus obtained by boiling it with alcohol.

c. From Dandelion-roots. Obtained in the same way as from dahlia-tubers. (Wittstein, Repert. 71, 362; Herberger, Repert. 52, 399).

d. From Chicory-roots. The aqueous decoction is precipitated by neutral acetate of lead; the filtrate freed from lead is evaporated till a film forms on the surface; and the inulin which separates from it is purified by precipitating its aqueous solution with alcohol. (Woskresensky.)

e. From Lerp-manna. The substance is exhausted with boiling alcohol; the residue, consisting of starch, cellulose and inulin, is well boiled with water, and the inulin, which separates from the filtered extract on cooling, is collected and washed till the wash-water no longer exhibits the reactions of starch. (Anderson.)

Properties.—Inulin is a soft, white, tasteless, inodorous powder, resembling starch. When dried on glass or porcelain, it forms a translucent, brittle, dazzling white mass, which swells up in water. Specific gravity = 1·356 (Payen), 1·462 (Dubrunfaut). It is very hygroscopic, and sticks to the teeth and to moist paper. It exhibits lævo-rotatory power = 34° 42′. (Dubrunfaut, Compt. rend. xlii. 803.)

Most of the analyses which have been made of inulin agree nearly with the formula $C^6H^{10}O^5$. Woskresensky, however (J. pr. Chem. xxxvii. 309) obtained quantities of carbon and hydrogen much too large for this formula: he accordingly represents inulin by the formula $C^{24}H^{18}O^{14}$ (or $C^{24}H^{20}O^{14}$), and supposes that the inulin analysed by other chemists must have undergone partial oxidation; but the near accordance of most of these analyses renders this view improbable.

Inulin, immersed in cold water, or exposed to moist air, absorbs water, and crumbles to a dull-looking powder, consisting of *hydrated inulin*, $C^{12}H^{20}O^{10}.3H^2O$.

Inulin dissolves very sparingly in cold *water*, freely in boiling water, but the solution does not form a jelly like that of starch; it is insoluble in *alcohol*, which also precipitates it from its aqueous solution. It dissolves with brown colour in strong *sulphuric acid*, and is precipitated therefrom by ammonia, but not by water or alcohol. It is insoluble in *hydrochloric acid*, and in cold glacial *acetic acid*, but dissolves in the latter when warmed. The aqueous solution is not precipitated by *chlorine-water*, but forms a white precipitate with *infusion of galls*.

Inulin absorbs 3 per cent. *ammonia*, and dissolves in cold aqueous *potash*, forming a solution which leaves on evaporation a nearly colourless gum, and when mixed with acids, deposits, after a while, unaltered inulin.

Inulin dissolves in aqueous *cuprammonia* (an ammoniacal solution of cupric oxide), without previous tumefaction (Cramer, J. pr. Chem. lxxiii. 16), the solution yielding after a few hours, a copious blue amorphous precipitate, insoluble in water and in ammonia, soluble in tartaric and nitric acids (Schlossberger, J. pr. Chem. lxxiii. 373). It dissolves gradually in aqueous *nickel-ammonia*. (Schlossberger.)

The aqueous solution of inulin forms a white precipitate with *baryta-water*, and with chloride of barium mixed with potash.

Digitized by Google

It does not precipitate aqueous *acetate of lead*, either neutral or basic, but with a solution of the neutral acetate containing ammonia, it forms a white precipitate containing quantities of lead-oxide varying in amount from 51·23 to 62·43 per cent. It is not precipitated by *ferrous, ferric*, or *cupric sulphate, mercuric nitrate, nitrate of silver*, or *chloride of gold*.

Decompositions.—1. Inulin heated above 100° melts, with colouring and loss of weight, and is converted into a pitchy, sweetish substance, very soluble in water (Braconnot), insoluble in water and in alcohol (Payen). By dry distillation it yields acetic acid, having a brown colour, but free from oily matter. When thrown on glowing coals, it emits the odour of burnt sugar.—2. Heated with *water* to 100°, it is slowly but completely converted into non-crystallisable, lævo-rotatory, fermentable sugar.—3. By boiling with *nitric acid*, inulin is converted into malic, oxalic, and acetic acids, but not into mucic acid. Its solution in fuming nitric acid is not precipitated by water.—4. When heated with strong *sulphuric acid*, it turns yellow, then brown, and is ultimately carbonised.—5. By *dilute acids*, either hot or cold, inulin is converted into sugar, without evolution or absorption of gas.—6. Aqueous *arsenic acid* dissolves inulin, with aid of heat; after continued action, the cooled solution no longer deposits inulin, but leaves, on evaporation, a rose-coloured mass, which afterwards becomes darker, and finally black, grape-sugar being first formed, afterwards formic and ulmic acids.—7. *Oxide of lead* converts inulin wholly or partially into glucic acid, which, if afterwards exposed to the air, is changed into apoglucic acid. A warm aqueous solution of inulin reduces other salts of lead, also those of copper and silver. When an ammoniacal solution of acetate of lead is precipitated by aqueous inulin, the filtrate separated from the white precipitate deposits spangles of lead after a few hours, and contains formic acid.—8. Inulin is not *fermentable*. Neither its rotatory power nor any of its other properties is altered by *diastase*.—9. It is digested in the stomach, and does not pass, as inulin, either into the urine or into the fæces.

Inulin is distinguished from starch by its reaction with *iodine*, which imparts to it only a fugitive brown colour; by its solubility in aqueous cuprammonia, by its power of reducing certain metals from their solutions; and by its inalterability under the influence of ferments.

IODACETIC ACID. $C^2H^3IO^2 = \left.\begin{matrix}C^2H^2IO\\H\end{matrix}\right\}O$. (Perkin and Duppa, Phil. Mag. [4] xviii. 54.)—This acid is obtained, as an ethyl-compound, by the action of iodide of potassium on bromacetate of ethyl diluted with three measures of alcohol, the mixture being digested at 40° in the dark for about two hours, and the iodacetic ether then distilled off. To obtain the free acid, the ether is converted into a barium-salt by digestion with hydrate of barium; this salt is decomposed by cautious addition of sulphuric acid; and the filtrate is crystallised in a vacuum.

Iodacetic acid forms thin, tough, colourless, rhombohedral plates, having a very sour taste, and not deliquescent. It melts at 82°, with slight decomposition, and solidifies again at 85°. It is decomposed, like bromacetic acid, by moist oxide of silver, with formation of glycollic acid:

$$C^2H^3IO^2 + AgHO = AgI + C^2H^4O^3.$$

Iodacetate of Ammonium is very soluble, crystalline, and non-deliquescent. The *potassium*-salt exhibits similar properties. The *barium*-salt, $C^2H^2IBaO^2$, is crystalline, moderately soluble in water, and precipitated by alcohol. The *lead-salt* crystallises in prisms, but easily splits up in solution into iodide of lead and glycollic acid:

$$C^2H^3IPbO^2 + H^2O = PbI + C^2H^4O^3.$$

Iodacetate of Ethyl is an oily liquid, heavier than water, and having a very irritating odour. *Iodacetate of Amyl* is oily, heavier than water, has the odour of pears, and gives off an irritating vapour.

Di-iodacetic Acid. $C^2H^2I^2O^2$. (Perkin and Duppa, Chem. Soc. Qu. J. xiii. 1.)—The ethyl-compound of this acid, obtained by acting on dibromacetate of ethyl with iodide of potassium, is converted into a calcium-salt by means of milk of lime; the calcium-salt is decomposed by hydrochloric acid, avoiding an excess; and the solution is left to crystallise. The acid is thus obtained as a beautifully crystalline sulphur-yellow compound, volatile at ordinary temperatures, and slightly soluble in water. It has a faintly acid taste, with metallic after-taste. It does not blister the skin.

The *di-iodacetates* are slightly yellow, crystalline, and permanent, excepting the potassium and sodium-salts, which are deliquescent. The *barium*-salt, $C^2HI^2BaO^2$, forms rhombohedral crystals, which give off iodine when heated. The *calcium*-salt forms yellow silky needles, also decomposed by heat. The *lead*-salt, $C^2HI^2PbO^2$, is

Digitized by Google

obtained as a crystalline precipitate by adding a solution of the sodium-salt to acetate of lead, both being largely diluted. The *silver*-salt, prepared in like manner, forms a yellow crystalline powder, which, when gently heated, decomposes with slight explosion and evolution of iodine.

Di-iodacetate of Ethyl, $C^2H(C^2H^5)I^2O^2$, is a yellowish liquid, having a pungent, burning taste, and extremely irritating odour. It is insoluble. or nearly so, in water. Ammonia rapidly converts it into di-iodacetamide, $N.H^2.C^2HI^2O$, which is a pale yellow substance, sparingly soluble in water.

IODACETYL. C^2H^2IO.—The radicle of iodacetic acid.

IODAL. $C^2HI^3O = C^2I^3O.H$. *Hydride of Tri-iodacetyl* (i. 34).—This compound is said to be obtained by adding iodine to a mixture of alcohol and nitric acid. The iodine rapidly disappears, and an oil separates which may be purified by agitation with water and distillation over chloride of calcium. It begins to boil at 25°, but the boiling point gradually rises to 115°. Potash converts it into iodoform (Aimé, Ann. Ch. Phys. [2] lxiv. 217). Johnston (Phil. Mag. [3] ii. 215) obtained, by a similar process, an oily liquid which boiled at 110°, but decomposed and turned brown at the same time. Johnston regarded the product as iodate of ethyl (see Gmelin's Handbook, ix. 186). Schoonbroodt (Bull. Soc. Chim. de Paris, 1861, p. 109), by adding hypochlorite of potassium to an alcoholic solution of iodine till the latter was decolorised, obtained a copious precipitate consisting of small shining needles, easily soluble in water, sparingly in alcohol, and resolved by potash-ley into formic acid and iodoform: hence it was probably iodal.

IODAMIDES and **IODAMMONIUMS.** Under these terms may be included a number of compounds, mostly of an explosive character, produced by the action of iodine on ammonia. The composition and properties of these products vary according to the mode of preparation adopted.

I. **Iodamides.** By digesting iodine in excess of aqueous ammonia; by adding a large excess of aqueous or alcoholic ammonia to a saturated solution of iodine in alcohol, and then diluting with water; by adding ammonia to a solution of iodine in nitro-muriatic acid (which contains protochloride of iodine, ICl); or by decomposing the explosive compound called chloride of nitrogen, with iodide of potassium—a black powder is precipitated which when dry is violently explosive. It must be collected on a filter, and washed with water; and to guard against accidents in drying, it is advisable to divide the filter, with the moist precipitate upon it, into small pieces, and expose them to warm dry air at considerable distances from each other. Or the precipitate may be dried under a receiver filled with ammonia gas, in which case, according to Millon, there is no fear of explosion.

The product obtained by either of these processes, commonly called iodide of nitrogen, is a brownish-black soft powder, which when dry explodes from the slightest cause, producing a loud report and destroying any solid bodies that may be near it. The explosion is attended with a faint flash of violet light, nitrogen being set free as gas, and iodine in the form of very fine powder. It may be exploded by friction, even under water, and in the dry state can scarcely be touched without exploding, the slightest elevation of temperature, and even the friction produced by sliding over the surface of smooth paper, being sufficient to explode it. When moist, it decomposes slowly in contact with the air, yielding nitrogen, iodic acid, and hydriodic acid. A similar decomposition is produced more rapidly by boiling *water*, or by *alkaline solutions*. *Sulphydric acid* decomposes it, producing hydriodic acid, ammonia, and a deposit of sulphur. With *sulphurous acid*, it yields iodide of ammonium, hydriodic acid, and sulphuric acid. *Bromine-water* decomposes it instantaneously, *chlorine* more slowly: strong *nitric acid* attacks it violently. (Gladstone.)

This description applies to all the products obtained by the processes above-mentioned; nevertheless, these products are not absolutely identical in composition; but they all appear to be iodamides—that is to say, ammonia-molecules having the hydrogen more or less replaced by iodine—combined in some instances with ammonia itself. Gay-Lussac regarded the product of the action of iodine on ammonia as a compound of iodine and nitrogen alone, in fact, as tri-iodamide, NI^3, and, according to recent analyses by Stahlschmidt (see p. 281), this compound does appear to be formed under certain conditions; but repeated experiments by several chemists have shown that the explosive compound thus produced frequently also contains hydrogen: for when small portions of it in a state of perfect dryness are repeatedly exploded under a bell-jar, iodide of ammonium is deposited on the sides of the vessel.

According to Millon (Ann. Ch. Phys. [2] lxix. 78), the compound is mono-iodamide, NH^2I, and the decomposition just mentioned takes place as represented by the equation:

$$2NH^2I = NH^4I + I + N.$$

Digitized by Google

Bineau (*ibid.* [3] xv. 71), by determining the quantities of hydriodic acid, ammonia, and nitrogen produced in its decomposition by sulphydric acid, was led to adopt the formula, NHI^2, which is that of di-iodamide:

$$NHI^2 + 2H^2S = NH^4I + HI + S^2.$$

Gladstone (Chem. Soc. Qu. J. iv. 34) takes the same view of its constitution. By decomposing with sulphydric acid, the compound produced by the action of ammonia on an alcoholic solution of iodine, he finds that it contains 2 at. iodine to 1 at. nitrogen, while its decomposition by aqueous sulphurous acid is represented by the equation:

$$NHI^2 + 2SH^2O^2 + 2H^2O = NH^4I + HI + 2SH^2O^4.$$

He also finds that the formula NHI^2 is in accordance with the formation of the compound by the action of hypochlorite of calcium or iodide of ammonium (observed by Playfair), that reaction being attended with evolution of ammonia, according to the equation:

$$CaCl^2O^2 + 2NH^4I = NHI^2 + CaCl^2 + 2H^2O + NH^3.$$

Bunsen (Ann. Ch. Pharm. lxxxiv. 1) has also examined the constitution of iodide of nitrogen, and arrived at different conclusions. He observes that the mode of formation of the explosive compound from iodine and ammonia, with hydriodic acid as the only secondary product, shows that it must be a substitution-product of ammonia, of the form NI^3, NHI^2 or NH^2I, associated at most with ammonia and hydriodic acid; 2. That it cannot contain hydriodic acid, because it dissolves in hydrochloric acid without evolution of gas, and forms a solution containing ammonia and protochloride of iodine, but no hydriodic acid; 3. That, to determine its composition, it is sufficient to ascertain how much ICl and how much NH^3 it yields with hydrochloric acid, and to see which of the following equations agrees with the results:

$$\begin{aligned}
NI^3 + 3HCl &= 3ICl + NH^3 \quad . \quad . \quad . \quad . \quad (a)\\
NHI^2 + 2HCl &= 2ICl + NH^3 \quad . \quad . \quad . \quad . \quad (b)\\
NH^2I + HCl &= ICl + NH^3 \quad . \quad . \quad . \quad . \quad (c)\\
NH^2I + NH^3 + HCl &= ICl + 2NH^3 \quad . \quad . \quad . \quad . \quad (d).
\end{aligned}$$

Preparations obtained by mixing cold and more or less saturated anhydrous alcoholic solutions of iodine and ammonia, which were not decomposed by washing with absolute alcohol, gave, when dissolved in hydrochloric acid, quantities of ammonia, iodine, and chlorine, in the atomic proportion of 2 : 3 : 3, showing that the constitution of the compound thus formed was $NI^3.NH^3$. A preparation obtained by adding ammonia to a solution of iodine in nitro-muriatic acid diluted with water, and washed as quickly as possible with cold water, gave, with hydrochloric acid, quantities of ammonia and protochloride of iodine in the atomic proportion of 5 : 12, showing that its formula was $4NI^3.NH^3$. When washed with water for any length of time, even till the greater part of the compound was decomposed, with separation of iodine and nitrogen, the undecomposed portion still yielded more than 1 at. ammonia to 3 at. chloride of iodine, a proof that ammonia entered essentially into its constitution. Bunsen is of opinion that there exist two distinct compounds, $NI^3.NH^3$ and $4NI^3.NH^3$, formed in the manner shown by the equations,

$$\begin{aligned}
2NH^3 + 6I &= NI^3.NH^3 + 3HI\\
8(NI^3.NH^3) + 3H^2O &= 2(4NI^3.NH^3) + 3(NH^4)^2O.
\end{aligned}$$

The formation of the so-called iodide of nitrogen by the action of ammonia on a solution of iodine in nitro-muriatic acid, would be inconsistent with this view, if that solution contained, not ICl, but, as is sometimes supposed, ICl^3, because NI^3 could not be formed from the latter. Bunsen has, however, shown that the solution of iodine in nitro-muriatic acid contains only ICl. The formation of the explosive compound from ICl is explained by the equation,

$$2NH^3 + 3ICl = (NI^3.NH^3) + 3HCl.$$

The immediate products of its explosion are nitrogen and hydriodic acid:

$$NI^3.NH^3 = N^2 + 3HI.$$

which latter is, for the most part, resolved by the high temperature into iodine and hydrogen, while another portion unites with the ammonia of the compound, forming iodide of ammonium, thereby setting free quantities of iodine and nitrogen equivalent to this ammonia.

The compound obtained by Bineau and by Gladstone, *viz.* di-iodamide NHI^2, is intermediate between the two compounds obtained by Bunsen:

$$2N^2I^3H^3 + N^2I^{12}H^3 = 9NHI^2$$

Digitized by Google

Bunsen's first compound $NI^3.NH^3$, may be represented as tri-iodammonammonium, $N\left\{\begin{matrix}H^2\\NHI^2\end{matrix}\right.$, and the second compound $4NI^3.NH^3$, might be formulated in a similar manner.

Lastly, it appears from the experiments of Stahlschmidt (Pogg. Ann. cxix. 421; Bull. Soc. Chim. de Paris 1864, p. 149), that di- or tri-iodamide may be produced according as alcoholic or aqueous ammonia is added to an alcoholic solution of iodine. By mixing alcoholic solutions of ammonia and iodine, he obtained a compound yielding by analysis quantities of iodine and nitrogen in the proportion of 2 at. I to 1 at. N, therefore NHI^2.

On the other hand, a product obtained by adding aqueous ammonia to an alcoholic tincture of iodine, yielded by decomposition with *sulphydric acid*, products containing 3 at. I to 1 at. N, according to the equation,

$$NI^3 + 3H^2S = NH^4I + 2HI + S^2.$$

The same substance treated with *iodide of methyl*, yielded in 24 hours, two layers of liquid, the upper consisting of aqueous hydriodic acid and iodide of ammonium, while the lower contained iodoform and penta-iodide of tetramethyl-ammonium:

$$2NI^3 + 3CH^3I = 2NH^3 + \underset{\text{Iodoform.}}{3CHI^3},$$

$$\text{and } 2NI^3 + 9CH^3I = 2HI + \underset{\text{Iodoform.}}{CHI^3} + \underset{\text{Penta-iodide of tetramethyl-ammonium.}}{2N(CH^3)^4I^5}.$$

On treating the lower liquid with boiling absolute alcohol, a solution was obtained which deposited the penta-iodide in shining green crystals, while iodoform remained in the mother-liquor; and this mother-liquor being treated with potash, gave off ammonia and yielded iodoform, together with yellow crystals having the composition of di-iodomethylamide $N\left\{\begin{matrix}I^2\\CH^3\end{matrix}\right.$. The saline residue contained butyrate of potassium and other salts.

If the tri-iodamide used in the preceding reaction still retains ammonia, the products obtained are penta-iodide of tetramethylammonium, and a compound of 2 at. iodoform with mono-iodide of tetramethylammonium, $C^6H^{14}NI^7 = (CH^3)^4NI + 2CHI^3$.

By acting with ammonia on penta-iodide of tetramethylammonium (which contains 4 at. iodine in a state of less intimate combination than the fifth, and ready to act like free iodine), Stahlschmidt has obtained a compound containing $C^4H^{13}N^2I^5$, which may be regarded as a compound of di-iodamide, NHI^2, with tri-iodide of tetramethyl-ammonium. The same compound is formed on mixing alcoholic tincture of iodine with an ammoniacal solution of mono-iodide of tetramethyl-ammonium. It is a black powder, which explodes at 100°, or in contact with sulphuric acid, giving off nitrogen, and leaving the penta-iodide. The same decomposition takes place on heating its alcoholic solution. Sulphydric acid reduces it to mono-iodide of tetramethylammonium. Nitric acid decomposes it slowly. Heated with potash, it yields iodoform. It is insoluble in most liquids, but dissolves slightly in absolute alcohol. (Stahlschmidt.)

II. **Iodammonium.** NH^3I; or *Iodide of Ammonia*, $NH^3.I$. — Dry iodine absorbs dry ammonia-gas, 100 parts of iodine taking up 8·3 pts. of ammonia at + 10°, 9 pts. at 0°, and 9·4 pts. at −18°. The product is a blackish-brown very tenacious liquid, having a metallic aspect, smelling of ammonia and iodine, and imparting a brown stain to the skin and to paper. When heated, it gives off a portion of the ammonia and sublimes in violets vapours. Its lustre and tenacity are destroyed by excess of ammonia. It dissolves readily in alcohol, and is resolved by water into iodide of ammonium and di-iodamide:

$$2NH^3I = NH^4I + NH^2I.$$

In a current of hydrochloric acid gas, it is completely decomposed, yielding nitrogen gas, sal-ammoniac, iodide of ammonium, and free iodine. (Millon, Ann. Ch. Phys. lxix. 78.)

According to Bineau, 100 pts. iodine absorb 20·55 pts. ammonia-gas, yielding a product having the composition $N^3H^9I^2$. This may be represented as an *iodide of iod-ammon-ammon-ammonium* $\left[N\left\{\begin{matrix}H^3\\N\left\{\begin{matrix}H^2\\NH^3I\end{matrix}\right.\end{matrix}\right.\right].I$.

Millon's compound, if its composition has been correctly determined, is remarkable as presenting the only known instance of an ammonium-molecule existing in the free state.

III. **Iodide of Iodammonium.** $NH^3I^2 = (NH^3I).I$. —This compound, discovered

Digitized by Google

by Guthrie (Chem. Soc. J. xvi. 239), is obtained: 1. By adding finely-powdered iodine to a saturated solution of nitrate or carbonate of ammonia mixed with about one-third of an equivalent quantity of potash. The iodine immediately liquefies, without perceptible rise of temperature, and unites with the elements of the ammonia, forming a very mobile brownish-black liquid, while the supernatant solution remains colourless. The iodide of iodammonium is separated by a pipette from the saline solution.—2. A similar, and probably identical liquid is obtained by adding to the solution of nitrate of ammonia, mixed with potash, a saturated solution of iodine in aqueous iodide of potassium.

Iodide of iodammonium dissolves in ether, alcohol, chloroform, sulphide of carbon, and aqueous iodide of potassium. When heated, it is partly resolved into iodine, and an iodiferous liquid, which may be distilled without decomposition, and is probably Millon's or Bineau's "iodide of ammonia."

$$NH^3I^2 = I + NH^3I.$$
$$3NH^3I^2 = I^4 + 3NH^3.I^2.$$

Exposed in the dry state to the air, it decomposes spontaneously into ammonia and iodine, no permanent gas being evolved. On agitating it in a eudiometer-tube with mercury, iodide of mercury is formed, and the mercury is depressed by the liberated ammonia, which latter is completely absorbed by water:

$$NH^3I^2 + Hg = NH^3 + HgI^2.$$

It is decomposed by water, colouring the water reddish-brown, from separation of iodine, evolving nitrogen gas, and yielding a residue of di-iodamide, which explodes spontaneously under water:

$$4NH^3I^2 + H^2O = 2NHI^2 + 2NH^4I + 2HI + H^2O = N^2 + 4HI + I^2 + 2NH^4I + H^2O$$

The formation of the di-iodamide is more rapid than its decomposition, so that some of it is left after the original compound is broken up.

The caustic *alkalis* effect the same decomposition as water, but more quickly, on account of the greater affinity of their metals for iodine.

Acids determine the formation of ammonia, *e. g.*:

$$NH^3I^2 + HCl = NH^4Cl + I^2.$$
$$NH^3I^2 + H^2SO^4 = (NH^4)^2SO^4 + I^2.$$

A portion of the compound prepared by the first method (p. 282) and decomposed in this way by dilute sulphuric acid, yielded in one experiment 5·92 per cent. NH^3 and 93·47 I, in another, 6·59 NH^3 to 63·04 I, the formula requiring 6·27 NH^3 to 93·73 I. On submitting the compound to fractional solution with chloroform, the residue was found to have exactly the same composition as the original substance, showing that the substance operated on was a definite compound, and not a mixture of two or more.

IODAMMONIUM. (See p. 282.)

IODANILINE. Syn. with Iodophenylamine. See Phenylamine.

IODANISIC ACID. $C^8H^7IO^3$. Produced, together with hydriodate of oxanisamic acid, by the action of hydriodic acid on diazoanis-oxanisamic acid:

$$\underset{\text{Diazoanis-oxanisamic acid.}}{C^8H^6N^2O^3.C^8H^9NO^3} + 2HI = \underset{\text{Hydriodate of oxanisamic acid.}}{C^8H^9NO^3.HI} + \underset{\text{Iodanisic acid.}}{C^8H^7IO^3} + N^2$$

It forms white needles, insoluble in water, easily soluble in alcohol and in ether. The *silver-salt* is a white amorphous precipitate. (P. Griess, Proc. Roy. Soc. x. 309; Jahresber. 1859, p. 466.)

IODHYDRINS. Compounds derived from glycerin or from glycide (ii. 896), by assumption of the elements of hydriodic acid and elimination of water. Only two have hitherto been obtained; both of which are glycidic ethers, viz.:—

Iodhydroglycide or Epi-iodhydrin . . $C^3H^5\{^{I}_{O}$ = $C^3H^6O^2 + HI - 2H^2O$.

Iodhydrodiglycide (Berthelot's Iodhydrin) $(C^3H^5)^2\{^{I}_{H}\{^{I}_{O^2}$ = $2C^3H^6O^2 + HI - 3H^2O$.

Digitized by Google

The first has been already described (ii. 899). The second is obtained by saturating glycerin with hydriodic acid, keeping the liquid in a close vessel at 100° for forty hours, and then treating it with potash and ether. It is a syrupy liquid of a golden yellow colour, and specific gravity 1·783. It has a saccharine taste, dissolves about o·1 -third of its bulk of water, but is not itself soluble in water. It is soluble in alcohol, and still more in ether. It is not volatile without decomposition. It burns without residue, giving off vapours of iodine. Potash decomposes it slowly at 100°, producing iodide of potassium, a liquid which appears to be identical with glycerin, and a volatile liquid, probably oxide of glyceryl ($C^3H^5)^2O^3$. The iodine in cod-liver oil is perhaps in the form of this, or a similar compound. (Berthelot and De Luca, Compt. rend. xxxix. 748.)

IODIDE OF BORON. See BORON (i. 627).

IODIDE OF HYDROGEN. IODHYDRIC OR HYDRIODIC ACID. HI. Iodine does not combine with hydrogen at ordinary temperatures, even under the influence of sunshine; but when hydrogen gas and iodine vapour are passed together through a red-hot tube, combination takes place. According to Blundell (Pogg. Ann. ii. 216), spongy platinum brings about the combination at ordinary temperatures. The affinity of iodine for hydrogen is inferior only to that of oxygen, fluorine, chlorine, and bromine; consequently iodine separates hydrogen from most of its combinations, *viz.* from phosphoretted hydrogen, sulphydric acid, ammonia, and many organic compounds, *e.g.* alcohol, ether, and volatile oils, the result being in all cases the formation of hydriodic acid (Gaultier; Colin). Iodine does not decompose *water*, even at a red heat, or at all events, produces mere traces of iodic and hydriodic acids (Gay-Lussac). If, however, there is likewise present any substance that can take up the oxygen of the water, hydriodic acid is produced in abundance. Hence water and iodine, in contact with *phosphorus*, form hydriodic acid and phosphorous acid (Gay-Lussac): with *sulphurous acid*, only however when a considerable quantity of water is present, they yield hydriodic and sulphuric acids. With *sulphites*, if largely diluted, the products are hydriodic acid and a sulphate; similarly with *hyposulphites;* with *arsenious acid*, hydriodic acid and arsenic acid; with *stannous salts*, hydriodic acid and a stannic salt; and with certain *metals*, hydriodic acid and a metallic oxide.

Preparation.—1. *In the gaseous state.*—*a.* 1 pt. of phosphorus and 9 pts. of iodine are moistened with a small quantity of water, or covered with moistened glass-powder, and heated in a retort connected with a mercurial trough. Towards the end of the operation, hydriodate of phosphamine (p. 201) may sublime. Personne (Compt. rend. lii. 468) recommends the use of amorphous phosphorus for this purpose. The phosphorus is to be introduced into a tubulated retort, covered with a layer of water, and iodine added by successive portions, while the whole is gently heated. A regular stream of hydriodic acid-gas is then given off quite free from iodine-vapour.—*b.* 1 pt. of phosphorus is gently heated with 14 pts. of iodide of potassium, 20 of iodine, and a small quantity of water. If the evolution of gas becomes too violent, the vessel must be plunged into cold water; if it becomes too slow, heat must be again applied (Millon, J. Pharm. xxviii. 299):

$$4KI + I^{10} + P^2 + 7H^2O = K^4P^2O^7 + 14HI.$$

2. *In the liquid state.*—Iodine and persulphide of hydrogen, which, when they come in contact, unite, and form a yellowish-brown liquid, are placed together at the closed end of a dry glass tube; and at a short distance from them, in a bend of the tube, is placed a small quantity of water. If the tube be then sealed, and the first-mentioned liquid brought in contact with the water, decomposition takes place, resulting in the separation of sulphur and hydriodic acid, a considerable portion of the latter condensing in the liquid state. (Kemp, Phil. Mag. [3] vii. 444.)

3. *In aqueous solution.*—The aqueous acid may be prepared by passing the gas obtained by either of the preceding methods into water, which absorbs it very rapidly and in large quantity; or directly: 1. By distilling iodine with phosphorus and a large quantity of water.—2. By passing sulphydric acid gas into water in which iodine is diffused, the liquid being well agitated all the while, till the iodine has disappeared, and the liquid, which was brown at first, has become colourless; the liquid is then filtered and heated to commencing ebullition, in order to expel the excess of sulphydric

distinguished by the following colours: Oxide of bismuth, brown; oxide
orange-yellow; mercurous oxide, greenish-yellow; mercuric oxide, scarlet;
silver, yellowish-white. Other metallic iodides remain dissolved in the liquid
that state may be regarded as hydriodates of metallic oxides. With *metallic p*
e.g. the peroxide of manganese or of lead, hydriodic acid forms a metallic io
hydriodate), water, and free iodine; *e.g.*

$$PbO + 2HI = PbI^2 + H^2O + I.$$

With many *organic compounds*, hydriodic acid reacts in the same manner
inorganic compounds, sometimes deoxidising them, with formation of water a
nation of iodine, sometimes simply exchanging its hydrogen for a radicle of the
compound. Examples of the first mode of action are afforded by *mannite*, wit
hydriodic acid yields iodide of hexyl, water, and iodine (p. 154), and by *eryt*
nite, with which it yields in like manner iodide of tetryl (ii. 505). An instan
second mode of action is exhibited by *salicylate of methyl* (wintergreen oil), wi
hydriodic acid forms iodide of methyl and salicylic acid. (Lautemann, *A*
Pharm. cxxv. 13.)

$$C^7H^5(CH^3)O^2 + HI = CH^3I + C^7H^6O^2.$$

It is by reactions of this kind that Matthiessen and Foster (Chem. Soc. J. x
have shown that cotarnine and its derivatives are methylised compounds
(Cotarnine, ii. 90; Hemipinic acid, iii. 142; Opianic acid, and Narcotine.)

Hydriodic acid unites directly with ammonia, phosphamine, and other
amines, phosphines, arsines, stibines, &c., forming salts, which may be regarde
as hydriodates of these ammonia-derivatives, or as iodides of the corresponding
tives of ammonium, *e.g.* hydriodate of triethylamine, $N(C^2H^5)^3.HI$, iodide of
ammonium, $[N(C^2H^5)^3H]I$. Similarly with other organic bases.

It likewise unites directly with many hydrocarbons containing even nu
hydrogen-atoms; the olefines and camphenes, for example. Greville Willi
distilling the hydrocarbons obtained from Boghead naphtha with fuming hydrio
obtained compounds which might be regarded as hydriodates of olefines, $C^nH^{2n}.$
iodides of the corresponding monatomic alcohol-radicles, $C^nH^{2n+1}I$, as whe
with alcoholic ammonia, they yielded the hydriodates of the corresponding
$C^nH^{2n+3}N.HI$. The hydriodates of the olefines are not, however, in all cases
with the corresponding monatomic alcoholic iodides; hydriodate of amylene
ample, is merely isomeric with iodide of amyl; for when treated with moist
silver, it yields a hydrate of amylene, not exhibiting the properties of commo
alcohol. Similarly with hydriodate of hexylene (p. 188).

IODIDE OF NITROGEN. See Iodamides (p. 280).

IODIDES, METALLIC. These compounds are obtained by the same
that yield the chlorides and bromides.

1. By the direct action of iodine on a metal, frequently even at ordinary temp
as in the case of mercury. The combination is attended with development
sometimes with flame, which is coloured violet by the iodine vapour (*e.g.* p
sodium).

2. By the action of iodine on certain metallic oxides, hydrates, or ca
Iodine displaces the oxides of potassium, sodium, barium, and calcium at a
and that of oxide of silver at ordinary temperatures. When solutions of ca
carbonated alkali are treated with iodine, mixtures of iodide and iodate are p
which last salt is decomposed by heat into iodide and oxygen. Iodine and
of barium, when mixed with water, decompose into iodide of barium and oxyg

$$I^2 + BaO^2 = BaI^2 + O^2.$$

3. By the action of certain metals, such as potassium, zinc, and iron, on hydrio
the metal then replacing the hydrogen.—4. By saturating hydriodic acid wit
hydrates, or carbonates. With a peroxide and hydriodic acid, iodine is libe
5. The insoluble iodides are prepared by adding hydriodic acid or the solut
metallic iodide to solutions of the heavy metals.

All iodides are destitute of metallic lustre; some of them are very be

Digitized by Google

coloured. Their specific gravity is often lower than the mean specific gravity of their constituents: such is the case with the iodides of potassium, lead, copper, and silver. (Boullay.)

But few metallic iodides are decomposed by heat alone; the iodides of gold, silver, platinum, and palladium, however, give up their iodine when heated. Most metallic iodides when ignited in open vessels, so that the air has excess to them, give up their iodine, and are converted into oxides; such, however, is not the case with the iodides of potassium, sodium, bismuth, and lead. *Chlorine*, at red heat, decomposes the metallic iodides, converting them into chlorides, and either setting the iodine free or forming chloride of iodine. *Bromine* acts in a similar manner. Chlorine-water likewise liberates the iodine. *Hydrochloric acid* gas decomposes metallic iodides at a red heat, forming hydriodic acid gas and a metallic chloride. Concentrated *sulphuric* and *nitric acid* and likewise *acid sulphate* of *potassium* decompose all metallic iodides on the application of heat, the products being iodine, which escapes in violet vapours (which give a blue colour to paper moistened with starch), and a sulphate or nitrate of the corresponding metal. When this change is produced by nitric acid, pernitric oxide is formed at the same time; sulphuric acid and acid sulphate of potassium evolve sulphurous anhydride, sometimes also sulphydric acid. Sulphuric acid or acid sulphate of potassium with peroxide of manganese, peroxide of lead, or chromate of potassium, produces the same decomposition, but without evolution of sulphurous anhydride. A bead of microcosmic salt saturated with *oxide of copper* communicates a beautiful green colour to the blow-pipe flame on the addition of a metallic iodide (Berzelius). Metallic iodides agitated with sulphuric acid and *sulphide of carbon*, communicate an amethyst-red tint to the latter.

Very few metallic iodides remain unaltered in contact with *water:* such, however, is the case with the iodides of bismuth, lead, copper, and several of the noble metals. Some of them are converted by water into an oxide, which is precipitated, and hydriodic acid which dissolves in the water (iodide of tin): or into a precipitated compound of iodide and oxide of the metal, and a solution of the iodide in aqueous hydriodic acid (the iodides of antimony and tellurium). Most metallic iodides are perfectly soluble in water; and the solution may be regarded as containing either the unaltered iodide, or a hydriodate of the oxide formed by double decomposition (*e.g.* the iodides of the alkali-metals, iron, nickel, cobalt, &c.).

The soluble iodides are extremely poisonous. When evaporated out of contact of air, they generally leave anhydrous metallic iodides, which partly separate in the crystalline form before the water is wholly driven off. The earthy hydriodates, however, are resolved, on evaporation, into the earthy oxides and hydriodic acid, which escapes. A very small quantity of *chlorine* colours the solution yellow or brown, by partial decomposition; and a somewhat larger quantity takes up the whole of the metal, forming a chloride (or hydrochlorate), and separates the iodine, which then gives a blue colour with starch; a still larger quantity of chlorine gives the liquid a paler colour, and converts the separated iodine into trichloride of iodine, which does not give a blue colour with starch, and frequently enters into combination with the chloride produced. Strong *sulphuric acid* and somewhat concentrated *nitric acid* colour the solution yellow or brown; and if the quantity of the iodide is large, and the solution much concentrated or heated, they liberate iodine, which partly escapes in violet vapours. *Starch* mixed with the solution, even if it be very dilute, is turned blue—permanently, when the decomposition is effected by sulphuric acid; for a time only when it is effected by nitric acid, especially if that acid be added in large quantity. If the sulphuric acid contains sulphurous acid, which is very likely to be the case with fuming oil of vitriol, it does not produce the blue colour, even when added in large excess. If a liquid in which iodine is present (urine, for example) contains much organic matter, which may decompose the sulphuric acid and form sulphurous acid, it will not produce the blue colour with starch and sulphuric acid unless it be diluted with water (Dupasquier, J. Pharm. 28, 218). If the solution likewise contains a salt of *iodic acid*, most acids produce a brown colour and separate iodine; because, by virtue of their affinity for the base of the iodate, they facilitate the mutual decomposition of the hydriodic and iodic acid: $IHO^3 + 5HI = 3H^2O + 3I^2$. The separation of iodine, and the blueing of the starch likewise takes place on adding hydrochloric acid to the solution, together with a stannic, ferric, or cupric salt, or a salt of chromic acid. Also, if the solution of the iodide be covered with gelatinous starch, the negative pole of a small voltaic battery immersed in the former, and the positive pole in the latter, the starch is turned blue in the neighbourhood of the positive wire, even if the solution contains a much larger quantity of bromide or chloride than of iodide (Steinberg, J. pr. Chem. xxv. 288). If the aqueous solution of a metallic iodide contains only $\frac{1}{10,000}$ part of iodine, it gives a strong blue colour with dilute gelatinous starch, on the addition of aqua-regia: with $\frac{1}{100,000}$ part of iodine, the

Digitized by Google

precipitate is violet; with $\frac{1}{500,000}$, rose-coloured; and with $\frac{1}{500,000}$, a pale rose-colour is produced after the lapse of a few hours (Harting, J. pr. Chem. xxii. 46). If the solution likewise contains a large quantity of metallic chloride, the blueing of the starch is not readily produced by the addition of nitric acid, in consequence of the formation of chloride of iodine: in this case, a solution of starch in boiling dilute sulphuric acid may be added to the solution of the iodide, and then a very small quantity of chlorine water, the liquid being stirred at the same time. (Berzelius.)

The aqueous solution of an iodide gives a brown precipitate with salts of *bismuth*; orange-yellow with *lead-salts*; dirty-white with *cuprous* salts, and also with *cupric* salts, especially on the addition of sulphurous acid; greenish-yellow with *mercurous* salts; scarlet with *mercuric* salts; yellowish-white with *silver*-salts; lemon-yellow with *gold*-salts; brown with *platinic* salts, first however turning the liquid dark brown-red; and black with salts of *palladium*, even when extremely dilute. All these precipitates consist of metallic iodides, many of them soluble in excess of the soluble iodide: the silver precipitate is insoluble in nitric acid and very little soluble in ammonia.

When iodine is added to an aqueous solution of a salt of hydriodic acid, the liquid takes up an additional quantity of iodine, equal, according to Baup (J. Pharm. ix. 46) to that which it already contains. It thereby acquires a dark-brown colour, and is supposed by some chemists to contain a *metallic polyiodide* or a salt of *hydriodous acid*; but the affinity by which the iodine is retained is very feeble.

Many metallic iodides absorb *ammonia* in definite proportions, forming compounds which may be regarded as iodides of ammonium-molecules, having part of the hydrogen replaced by a metal.

Some of these compounds unite with the *oxides* of the corresponding metals, forming **oxyiodides**, *e.g.* antimony and tellurium.

Metallic iodides also unite with one another, forming **double iodides** or **iodine-salts**.

IODIDES, ORGANIC. 1. *Acid.*—The iodides of acid organic radicles have not been much studied. Iodide of acetyl, C^2H^3OI, is obtained by the action of iodide of phosphorus on acetate of potassium or acetic anhydride; and iodide of benzoyl, C^7H^5OI, by the action of iodide of potassium on chloride of benzoyl. These acid iodides resemble the corresponding chlorides, but are much more easily decomposible.

2. *Alcoholic Iodides, Iodhydric* or *Hydriodic ethers.*— The monatomic alcoholic iodides are produced by the action of hydriodic acid, or iodide of phosphorus, on the corresponding alcohols, and by that of hydriodic acid on the corresponding diatomic hydrocarbons, *e.g.* iodide of amyl, $C^5H^{11}I$, from amylene, C^5H^{10}, and hydriodic acid. It is doubtful, however, whether the iodides obtained by this last process are really identical, or only isomeric with those obtained from the alcohols (p. 286).

The monatomic alcoholic iodides are less stable than corresponding chlorides, sometime decomposing under the influence of *light*, into the alcohol-radicle and free iodine, *e.g.* iodide of ethyl.

Heated in sealed tubes with certain metals, viz. *zinc*, *potassium*, or *sodium*, they yield a metallic iodide and the alcohol-radicle: *e.g.* zinc with iodide of ethyl; potassium or sodium with iodide of tetryl. With *mercury*, *tin*, *lead*, *arsenic*, *antimony*, and a few other metals, under the influence of heat, or of the sun's rays, they yield the iodides of organo-metallic bodies; thus, iodide of ethyl, enclosed in a sealed tube with stripe of tinfoil, and heated in a sealed tube to 180°, or exposed to the sun's rays concentrated by a lens or mirror, yields iodide of stannethyl, $(C^2H^5)^2SnI^2$ (ii. 235). Sometimes the organo-metallic compound thus formed acts further on the iodide, giving rise to new products (ii. 533, 535). Similar reactions take place when the alcoholic iodides are heated with the arsenides, antimonides, stannides, &c. of potassium or sodium, the organo-metallic radicles being then formed with greater facility, because the alkali-metal unites with the iodine.

The alcoholic iodides, heated in sealed tubes with *ammonia*, yield a mixture of the iodides of various ammonium-bases, in which the hydrogen of the ammonium is more or less replaced by the alcohol-radicle; thus, iodide of methyl with ammonia yields a mixture of the iodides of ammonium, and of methyl-, dimethyl-, trimethyl-, and tetramethyl-ammonium. With *primary* and *secondary monamines*, they react in a similar manner, the reaction becoming less complex as the amine itself is of a higher order. With *tertiary monamines* they unite directly, yielding the iodides of ammonium-bases in which the hydrogen is wholly replaced by the alcohol-radicle, *e.g.*

$(C^2H^5)^3N$	+	C^2H^5I	=	$(C^2H^5)^4NI$
Triethyl-amine.		Iodide of ethyl.		Iodide of tetrethyl-ammonium.

Iodide of ammonium has been found in gas-water, in the coke left and in the ashes of coal and peat from various localities.

Chatin (Compt. rend. xxx. 352; xxxi. 280; xxxii. 669; xxxiii. 519 found iodine in the waters of various streams and rivers, in quantity i the proportion of iron present, and more abundantly in the waters o tricts than in those from the oolitic and limestone formations; also in of Paris, Pisa, Florence, and other localities; but none in the rain-w tainous districts. He also states that it is sometimes present in the localities; but Lohmeyer (Phil. Mag. [4] vi. 237), Macadam (Che vi. 166) and others have failed to detect its presence in the air. Maca iodine in commercial potash, in various samples of alkaline carbonates (us in the ashes of wood-charcoal, in coals, and in numerous plants.

Preparation.—I. From *varec* or *kelp*. The material is exhausted w the solution is freed as much as possible, by evaporation and cooling, tallised salts contained in it (chloride of potassium, chloride of sodium sodium, sulphate of sodium, &c.); and the mother-liquor—which, be sodium, still contains sulphide and hyposulphite of sodium, and a port already mentioned*—is subjected to one of the following processes: 1. a subliming apparatus with oil of vitriol:

$$2NaI + 2H^2SO^4 = Na^2SO^4 + 2H^2O + SO^2 + I^2$$

This method is not very advantageous, because the sulphurous acid evo the iodine and the water which is present, in such a manner as to pro and sulphuric acids. (Soubeiran.)

2. The mother-liquor is heated in a subliming apparatus with pe ganese and sulphuric acid (Wollaston):

$$2NaI + 2H^2SO^4 + MnO^2 = Na^2SO^4 + MnSO^4 + 2H^2O +$$

Mr. Whytelaw, of Glasgow, adds one measure of oil of vitriol, careful portions at a time, to eight measures of the mother-liquor contained in —whereupon, carbonic anhydride and sulphydric acid (from the sulphide first evolved; and, after exposure to the air for a day or two, sulphu (from the hyposulphite of sodium) escapes, and sulphur is precipita pours off the liquid from the crystallised sulphate of sodium into a placed horizontally in a sand-bath, and fitted with a head, the beak o into the first of three tubulated receivers luted one into the other; hea to 65° C. (149° F.); and, after adding the peroxide of manganese and head, gradually raises the temperature to 100°, but not higher, becau (244° F.) chloride of iodine begins to distil over. Sometimes also cy collects in the last receiver in white, needle-shaped crystals. The liquid in the retort still contains iodine, and on cooling, deposits crystals of iod double iodide of lead and sodium.

3. The mother-liquor is evaporated to dryness, the residue heated w manganese, and the iodine precipitated from the filtered solution by chl Barruel's method, which is carried out as follows:—The residue obta rating the mother-liquor to dryness is mixed with $\frac{1}{10}$ of its weight manganese, and the mixture heated in an iron vessel to commencing re all the while), but not high enough to cause the evolution of vapours heat is continued till a sample of the mixture treated with sulphuric evolves sulphydric acid or deposits sulphur; that is to say, till the sulphide and hyposulphite of sodium are converted into sulphate. Th dissolved in such a quantity of water that the solution may have a sponding to 36° of Baumé's hydrometer; chlorine gas is passed throu liquid, which is constantly stirred, till a sample treated with more chlo gives a precipitate of iodine (excess of chlorine would convert the iodin and redissolve it), and the pulverulent precipitate of iodine is collect and purified by sublimation. Mohr is of opinion that a loss of iodin this process during the heating of the evaporated residue with mangane

4. The mother-liquor is precipitated by a copper-salt and metallic cuprous iodide heated with peroxide of manganese (Soubeiran). Th is diluted with water, and mixed with a solution of sulphate of copper, precipitate is produced:

$$4NaI + 2CuSO^4 = 2Na^2SO^4 + Cu^2I^2 + I^2;$$

the liquid containing the free iodine is separated by decantation and

* A mother-liquor from *varec*, examined by Soubeiran, contained no carbonate or s cipal salts contained in it, in addition to the iodides, were the nitrates of calcium and

Digitized by Google

the precipitated cuprous iodide, and mixed with sulphate of copper and iron filings till it no longer smells of iodine:

$$I^2 + 2CuSO^4 + Fe^2 = Cu^2I^2 + 2FeSO^4;$$

and the cuprous iodide thus produced is quickly separated by elutriation from the excess of iron-filings and from the liquid, before the ferrous sulphate has time to oxidate in the air. The two portions of iodide, obtained as above, are next dried at a gentle heat (a stronger heat would decompose the cuprous iodide, since it is mixed with basic ferric sulphate, and evolve iodine); the whole is mixed with twice or three times its weight of peroxide of manganese, and a sufficient quantity of sulphuric acid to form it into a paste; and the mixture is strongly heated in a subliming apparatus:

$$Cu^2I^2 + 2MnO^2 + 4SH^2O^4 = 2CuSO^4 + 2MnSO^4 + 2H^2O + I^2;$$

or the sulphuric acid is dispensed with, and a stronger heat applied:

$$Cu^2I^2 + 3MnO^2 = 2CuO + Mn^2O^4 + I^2.$$

In both cases, the iodine which passes over is accompanied by water derived from the hydrated cuprous iodide, from the sulphate of calcium precipitated with it, and from the sulphuric acid when it is used in the process. This water holds in solution a portion of the iodine, which may be again precipitated by sulphate of copper. By this process, 100 pts. of the mother-liquor yield 1 pt. of iodine.

II. *From the mother-liquor of the Caliche of Peru.*—This mother-liquor contains, according to Reichardt's analysis:

Nitrate of sodium	23·300
Chloride of sodium	8·594
Sulphate of magnesium	2·214
Chloride of magnesium	1·121
Iodate of sodium	0·440
Water, given off at 100°	57·406
Combined water (and loss)	6·925
	100·000

According to Grüneberg (J. pr. Chem. lx. 172), part of the iodine in this liquid is in the form of iodide of magnesium, which is decomposed, during the evaporation, into magnesia and hydriodic acid, thereby occasioning loss of iodine; this however may be prevented by the addition of caustic soda. The liquor is then treated with iron filings and sulphate of copper (as in Soubeiran's method) till the whole of the iodine is precipitated as ferrous and cuprous iodide:

$$\underset{\text{Iodate of sodium.}}{4NaIO^3} + 2CuSO^4 + Fe^{12} = Cu^2I^2 + FeI^2 + 2FeSO^4 + 10FeO + 2Na^2O;$$

and the precipitate, which also contains oxychloride of copper, is distilled with peroxide of manganese and sulphuric acid. The receiver contains crystals of iodine and chloride of iodine. The latter is heated with carbonate of potassium, which separates all the iodine, with formation of chloride and chlorate of potassium.

Jacquelin and Favre extract the iodine from the mother-liquors of caliche and commercial nitrate of sodium, by the following process, founded on the action of sulphurous acid on the iodates:

$$Mg(IO^3)^2 + 5H^2SO^3 = MgSO^4 + 4H^2SO^4 + H^2O + I^2.$$

The solution of the nitre having been concentrated to 36° or 37° Bm., a sample of it is mixed with aqueous sulphurous acid, cautiously and with constant stirring, until all the iodine is precipitated; the quantity of sulphurous acid used is then noted; and from the data thus obtained, the manufacturing operations are managed.

The solution of the nitre is run into a cistern built of stone or fire-bricks, and closed with a cover coated on the under side with glass plates. The cistern is fitted with an agitator, having stoneware arms worked from above through the cover, while the solution of sulphurous acid is being mixed with the liquid. The iodine which precipitates is collected, washed, and sublimed as above.

If the iodine is present in the form of iodide and iodate together, both chlorine and sulphurous acid must be employed, the necessary quantities having been previously ascertained by test-samples. If the iodate is present in the largest proportion, the chlorine-water is first used, and then the aqueous sulphurous acid; but when the iodate is the chief ingredient, the order of treatment is reversed.

III. *From Mineral waters.*—The quantity of iodine existing in certain mineral waters and in spent artificially iodised baths may be extracted by means of charcoal, which completely precipitates free iodine on the surface of its particles, where it

Digitized by Google

remains fixed like a dye upon cloth, and cannot be removed by hea
or by water or alcohol either hot or cold. Animal charcoal acts most p
lamp-black is recommended for the purpose on account of its chea
state of fine division. The water containing the iodine-compound havin
with a mixture of 1 pt. sulphuric to 2 pts. nitric acid, to set the i
run on to a filter filled with charcoal, and the charcoal thus iodised is
another filter, where it is mixed with hydrated protoxide of iron, whereby
converted into soluble iodide of iron, which may be obtained in the solid
porating in a current of hydrogen, or distilled with peroxide of manganese
acid in the usual way, to obtain iodine.

Purification.—The iodine obtained by either of the preceding proc
purified by washing with a small quantity of water, pressing between
and subliming a second time. According to Serullas, the iodine of com
completely purified by solution in alcohol, filtration, and precipitation w

For further details relating to the manufacture of iodine, see *Richardso
Chemical Technology*, vol. i. part 3, pp. 562–575.

Properties.—Iodine is at ordinary temperatures a crystalline solid, hav
black colour and metallic lustre, like plumbago or specular iron-ore. It
only in very thin slices, and then appears red by transmitted light.
and easily pulverised. It crystallises by sublimation in large brillia
plates, or in elongated octahedrons. Finer crystals are obtained from
exposing to the air an aqueous solution of hydriodic acid, or a solution of
The crystals belong to the trimetric system, having their axes in the rat

Iodine melts at 107° C. (224·6 F.), and solidifies in a lamellated m
It boils (when immersed in strong sulphuric acid) between 175° and
356° F.). In the open air it volatilises at ordinary temperatures, e
moist, diffusing an odour having considerable resemblance to that o
easily distinguished from it. Its vapour has a splendid violet colour (h
of the substance). The saturated vapour is so deep-coloured, that a strat
thick is impervious to daylight or candlelight. The colour is seen to g
when a quantity of iodine is thrown upon a hot brick. Iodine-vapou
heaviest of gaseous bodies, its specific gravity referred to air as uni
according to the experiments of Dumas, and 127 × 0·0693 = 8·801
from the atomic weight.

Iodine dissolves but sparingly in *water*, 1 pt. of iodine requiring 7,00
to dissolve it at ordinary temperatures. *Alcohol* and *ether* dissolve it
forming dark brown liquids. The alcoholic solution yields crystals of
poration, and is decomposed by water, which throws down the iodi
powder. Iodine also dissolves with facility in water containing solu
nitrate or *chloride of ammonium*, the solutions having a deep red co
containing 20 grains of iodine and 30 grains of iodide of potassium
water, is known as Lugol's solution, and is preferred in medicine t
tincture, because it is not decomposed by dilution with water. Iodin
sulphide of carbon, a very small quantity of it being sufficient to impart
very rich violet tint.

Iodine in its chemical reactions resembles chlorine and bromine, but i
and is displaced from most of its combinations by either of those bodie
colouring matters but slowly, and does not decompose water under the
sun's rays. It exerts a destructive action on organic tissues, producing
brown stain on the skin, paper, &c. This colour disappears after a w
influence of heat, if the contact has not been too much prolonged.

Iodine forms with *starch* a compound of a deep blue colour, soluble
but insoluble in acid and alkaline solutions. Its production affords
delicate test of the presence of iodine. If the iodine is in the free
colour is at once produced, but if it is in combination as a soluble iodid
takes place till the iodine is liberated by chlorine or nitrous acid (see Iod
p. 287). The blue compound is decolorised at a temperature of 70° o
176° F.), but recovers its colour as the liquid cools.

Iodine is employed in the laboratory for many chemical preparations,
starch. It was first introduced into medicine by Coindet of Geneva, w
with success for the treatment of goitre, either dissolved in alcohol, o
iodide of potassium, or as iodide of sodium; and since that applicatio
waters to which the virtue of curing goitre was ascribed, have been fo
iodine (Boussingault, Ann. Ch. Phys. liv. 163). On the other han
(Phil. Mag. [4] vi. 237) failed to detect iodine in the air and water of
tainous districts which are peculiarly free from goitre. Iodine appears t
action in causing the absorption of glandular swellings, and is also ad

Digitized by Google

tonic. Iodine swallowed in the solid state causes ulceration of the mucous membrane of the stomach, and death.

Iodine is extensively used in photography. The sensitive film of the daguerreotype plate consists of iodide of silver, produced by exposing a polished plate of the metal to the action of iodine-vapour; and surfaces of paper, collodion, albumin, &c. are rendered capable of taking photographic pictures by dipping them first in a solution of nitrate of silver and then in iodide (or sometimes bromide) of potassium.

IODINE, BROMIDES OF. Iodine forms with bromine a solid, volatile, crystalline compound, probably a protobromide, IBr (Balard), and with excess of bromine, a dark brown liquid, soluble in water, probably a pentabromide, IBr^5 (Löwig). On exposing the pentabromide together with a small quantity of water to a temperature below 0°, a crystalline hydrate is formed which at + 4° is resolved into water and bromide of iodine. (Löwig.)

IODINE, CHLORIDES OF. Iodine unites directly with chlorine, forming a protochloride and a trichloride, and perhaps also a pentachloride. There is also a tetrachloride produced by decomposition of the protochloride.

Protochloride. ICl.—Of this compound there are said to be two modifications, one liquid at common temperatures, the other solid; but the differences observed are perhaps due to the presence of small quantities of foreign substances, or to slight variations in the proportions of the chlorine and iodine. It is obtained:—1. By passing dry chlorine gas over dry iodine till the whole is liquefied, but no longer.—2. By distilling iodine with chlorate of potassium, oxygen being then evolved, the protochloride distilling over, and a mixture of chloride, iodate, and perchlorate of potassium remaining behind (Berzelius):

$$I^2 + 3KClO^3 = KClO^4 + KIO^3 + KCl + O^2 + ICl.$$

The protochloride of iodine obtained by either of these processes is described as a reddish-brown oily liquid, and nothing is said about its solidification (*Gmelin's Handbook*, ii. 346). According to J. Trapp also (J. pr. Chem. lxiii. 108), the liquid protochloride obtained as above does not solidify. But P. Schützenberger (*Zeitschr. Chem. Pharm.* 1862, p. 1) by passing dry chlorine in the cold over dry iodine (100 grms.) till it was liquefied, then adding more iodine (50 grms.), distilling between 100° and 102°, and rectifying between the same limits, obtained a liquid which crystallised in long needles when cooled to 10° in an open vessel, but if sealed up in a flask before it had time to solidify, retained its fluidity for 24 hours even when cooled to between 2° and 3°, and when the flask was opened, solidified suddenly, with rise of temperature, like a supersaturated solution of Glauber's salt. The crystals when exposed to the air, melted at 30° and solidified again at 25°. A similar result was obtained by introducing 31 grms. of iodine into a flask containing 8·7 grms. of chlorine (quantities proportional to the atomic weights). The whole of the chlorine was rapidly absorbed, and a liquid was formed which remained unaltered for many hours at 5° or 6°, but ultimately solidified completely.—By distilling iodine with chlorate of potassium, Schützenberger likewise obtained a dark-coloured liquid which quickly crystallised.

Trapp (*loc. cit.*) has also obtained the protochloride of iodine in the solid state by strongly heating iodine in a retort till it melted, and passing a stream of dry chlorine into the iodine-vapour till all the iodine had disappeared; the upper part of the retort then became filled with a thick red-brown vapour, and the solid protochloride of iodine collected in the receiver in large, hyacinth-red, transparent prisms and tables, which melted at 25° to a red-brown oily liquid.

Protochloride of iodine is very volatile; has a pungent odour of chlorine and iodine; attacks the eyes strongly; tastes slightly acid, strongly astringent and biting; stains the skin deep-yellow, and produces smarting. It decolorises *indigo* and *litmus*, but does not give a blue colour with *starch*. It deliquesces in the air, and according to Gay-Lussac, dissolves easily in *water* without decomposition; according to Schützenberger, on the other hand, it is decomposed by water, yielding iodic and hydrochloric acids, with separation of iodine, and formation of an iodised compound, which remains dissolved in the water, but may be extracted therefrom by ether. The protochloride dissolves in *alcohol* and in *ether*, forming yellow solutions.

Protochloride of iodine sometimes decomposes spontaneously into the tetrachloride and free iodine: $4ICl = ICl^4 + I^4$ (Kämmerer, J. pr. Chem. lxxxiii. 83).—When heated, it gives off the trichloride, leaving a residue of pure iodine: $3ICl = ICl^3 + I^2$ (Kane, Phil. Mag. [3] x. 430). *Sulphurous* and *sulphydric acids* decompose it with separation of iodine. With aqueous solutions of the fixed *alkalis* it yields a chloride and iodate and free iodine:

$$6KHO + 5ICl = 5KCl + KIO^3 + 3H^2O + I^4,$$

the iodine however dissolving in excess of the alkali in the form of iodide and iodate.

Digitized by Google

—With aqueous or alcoholic *ammonia*, it yields various iodamides (the so-called iodides of nitrogen (p. 289), according to the proportions used and the manner in which the reaction takes place, *e.g.*:

$$3ICl + NH^3 = 3HCl + NI^3. \text{ (Mitscherlich.)}$$
$$2ICl + NH^3 = 2HCl + NHI^2.$$
$$ICl + NH^3 = HCl + NH^2I.$$
$$3ICl + 2NH^3 = 3HCl + NI^3.NH^3. \text{ (Bunsen.)}$$

Mercuric chloride added to a concentrated aqueous solution of protochloride of iodine throws down mercuric iodide, leaving trichloride of iodine in solution (Kane):

$$4ICl + HgCl^2 = HgI^2 + 2ICl^3.$$

Stannous chloride added in small quantity to the concentrated aqueous solution, precipitates iodine, and is converted into stannic chloride: but on adding a larger quantity of the stannous chloride, the iodine disappears, and stannous iodide separates in brilliant orange-coloured needles (Kane):

$$2ICl + SnCl^2 = I^2 + SnCl^4.$$
$$2ICl + 3SnCl^2 = SnI^2 + 2SnCl^4.$$

Protochloride of iodine acts very readily on many organic compounds, the chlorine taking up an atom of hydrogen to form hydrochloric acid, and the iodine taking its place. In this way, many iodine-substitution-compounds may be obtained which could not be formed by the action of iodine alone; *e.g.*, iodopyromeconic acid, $C^5HI^2O^2$, from *pyromeconic acid*, $C^5H^4O^2$ (J. Brown, Edinb. Phil. Trans. xxi. [1] 49); mono- and di-iodophenic acids, from *phenic acid*, C^6H^6O (Sengenwald, Compt. rend. liv. 197). On the *alcoholic hydrides*, hydride of heptyl for example, protochloride of iodine acts in a manner opposite to that just mentioned, converting them into chlorides, with elimination of hydriodic acid (Schorlemmer, p. 144). In some cases, chloride of iodine unites directly with an organic compound, with *ethylene*, for example, forming chloriodide of ethylene, C^2H^4ClI (Maxwell Simpson, Proc. Roy. Soc. xii. 278). According to Geuther, however (Ann. Ch. Pharm. cxxiii. 123), when dry coal-gas is passed over fused protochloride of iodine, the ethylene contained in it is converted into dichloride of ethylene:

$$C^2H^4 + 2ICl = C^2H^4Cl^2 + I^2.$$

From iodised organic compounds it sometimes takes away one or more atoms of iodine, replacing them by chlorine; thus it converts *iodide of ethyl* into chloride of ethyl (Geuther):

$$C^2H^5I + ICl = C^2H^5Cl + I^2;$$

di-iodide of ethylene into chloriodide of ethylene (Maxwell Simpson):

$$C^2H^4I^2 + ICl = C^2H^4ICl + I^2;$$

or into dichloride of ethylene (Geuther):

$$C^2H^4I^2 + 2ICl = C^2H^4Cl^2 + I^4.$$

Benzene, C^6H^6, is violently attacked by protochloride of iodine, yielding chiefly crystalline chlorinated products of high boiling point, together with iodated bodies and free iodine.

Trichloride. ICl^3.—This compound is produced:—1. By treating iodine at a gentle heat with excess of chlorine gas.—2. By introducing finely divided iodic anhydride into dry hydrochloric acid gas; the mass then liquefies and boils, and on cooling deposits trichloride of iodine in long needles (Serullas):

$$I^2O^5 + 10HCl = 2ICl^3 + 5H^2O + Cl^4.$$

Also by mixing the crystallised iodic acid or anhydride with strong hydrochloric acid, the trichloride then crystallising out. (Soubeiran.)

Trichloride of iodine is orange-yellow, and crystallises on cooling after fusion in long needles (Serullas). It acts on other substances in the same manner as the protochloride (Kane); decolorises solution of indigo (Gay-Lussac); does not turn starch blue, except on the addition of an aqueous solution of stannous chloride, or other dechlorinating substance, which sets the iodine free.

It melts at a temperature between 20° and 25°, evolving chlorine gas, which it again absorbs on cooling (Serullas). In contact with a very small quantity of *water*, it is partly resolved into an insoluble yellowish portion (probably a mixture of trichloride of iodine and iodic anhydride), and a solution of protochloride of iodine and hydrochloric acid (Serullas):

$$4ICl^3 + 5H^2O = 10HCl + I^2O^5 + 2ICl.$$

may be prepared by boiling potato-starch or arrow-root with water and leaving it to cool. To obtain a delicate reagent, Béchamp (Zeitschr. Analyt. Chem. i. 466), recommends the following mode of preparation. Gelatinous starch is boiled with a quantity of concentrated potash-ley equal to $\frac{1}{10}$ of the weight of the dry starch contained in it, till it has become perfectly fluid; the liquid is then diluted with water, supersaturated with acetic acid, and precipitated with alcohol; and the bulky precipitate is boiled first with alcohol of 60 vol. per cent. then washed, first with alcohol acidulated with sulphuric acid, then with pure alcohol of the same strength, and dried. For use, the dried preparation is to be suspended in hot water.

When iodine exists in solution in the form of hydriodic acid or a metallic iodide, it may be separated by the addition of chlorine-water, sulphuric acid, or nitric acid, and will then give the blue colour with starch. When chlorine-water is used, care must be taken not to add an excess, as a chloride of iodine will then be formed which will not exhibit the starch reaction. (See IODIDES, p. 287.)

The methods of detecting iodine in insoluble iodides, and in presence of oxygen, sulphur, phosphorus, &c., are the same as those employed when it is to be estimated quantitatively.

Quantitative Estimation.—Iodine in the free state is best determined by means of a standard solution of sulphurous acid (see ANALYSIS, VOLUMETRIC, i. 265). When it occurs in the solution in the form of hydriodic acid or a metallic iodide, it may either be set free by *chlorine-water* and estimated volumetrically in the same manner; or it may be precipitated by *nitrate of silver* in the same manner as chlorine and bromine (i. 677, 903). 100 pts. of iodide of silver correspond to 54·128 pts. of iodine.

It may also be precipitated as iodide of palladium, by mixing the solution with chloride or *nitrate of palladium.* A black precipitate then falls, which settles down slowly but completely, and when ignited, leaves metallic palladium, 100 pts. of which are equivalent to 239·62 pts. of iodine.

This last method of precipitation serves also to separate iodine from bromine and chlorine. If the chlorine is also to be estimated, the precipitation must of course be made with nitrate of palladium, not with chloride. If bromine is present without chlorine, the iodine must be precipitated with chloride of palladium, because the nitrate would precipitate bromine as well as iodine; the precipitation of the bromine may however be prevented by the addition of a soluble chloride. To estimate the chlorine and bromine in the filtered liquid, the excess of palladium is removed by sulphydric acid and the excess of the latter by means of nitric acid or a ferric salt. The bromine and chlorine may then be precipitated by nitrate of silver, and the precipitate treated in the manner already described (i. 903). Iodine may also be estimated in presence of chlorine by the method already described (i. 678) for the estimation of bromine, viz., by precipitating the two elements with nitrate of silver and heating the silver precipitate in a stream of chlorine. The quantity of iodine is equal to the loss of weight multiplied by $\frac{127}{127 - 35{\cdot}5} = 1{\cdot}28$.

A precisely similar method may be applied to the determination of iodine in presence of bromine, the precipitate of iodide and bromide of silver being ignited in bromine-vapour, and the loss of weight multiplied by $\frac{127}{127 - 80} = 2{\cdot}70$.

For other methods of estimating iodine in presence of chlorine and bromine, see i. 678.

The method of decomposing *insoluble iodides*, so as to obtain the iodine in solution, are similar to those adopted for insoluble bromides (i. 678).

Iodates and *periodates* are reduced to iodides by the action of sulphurous or sulphydric acid. To decompose them by ignition would not give accurate results, as a portion of the iodine would be driven off.

The compounds of iodine with *phosphorus*, *arsenic* and *antimony* may be decomposed and analysed by treating them with water or aqueous alkalis, whereby the iodine is converted into hydriodic acid, and may then be precipitated with nitrate of silver from a solution acidulated with nitric acid. The iodides of *sulphur* are most readily analysed by heating them in a combustion-tube with nitrate of potassium and carbonate of sodium, whereby the iodine and sulphur are converted into metallic iodide and sulphate. (Guthrie, Chem. Soc. J. xiv. 59.)

Iodine in *organic compounds* may be estimated in the same manner as chlorine (i. 247). In the more easily decomposible compounds, such as the iodated organic acids, the iodine may also be determined by decomposing the compound with water and sodium-amalgam, then acidulating the solution with nitric acid, and precipitating with nitrate of silver. The same method may be applied to the corresponding bromine- and chlorine-compounds. (Kekulé, Ann. Ch. Pharm. Suppl. i. 338.)

alkaline liquid) on trichloride of iodine, which is yellow, reddens benzene, colours starch blue, and contains a salt having the composition NaI^3O or $NaIO.I^2$, that is, hypo-iodite of sodium with 2 atoms of free iodine, on the removal of which, either by excess of alkali, sulphurous acid, benzene, or other reagents, the hypo-iodite of potassium is immediately resolved into iodide and iodate. The alkaline solution of hypo-iodous acid is decomposed by iodide of potassium, yielding free alkali and free iodine, according to the equation:

$$KI + NaIO + H^2O = KHO + NaHO + I^2.$$

The subject requires further examination.

Periodic oxide, IO^2, and Oxides nearly allied to it in composition.

Periodic oxide is obtained, according to Millon, by treating with dilute alcohol the powder (p. 299) produced by the action of fuming nitric acid on iodine, regarded by Kämmerer as nitroso-iodic anhydride, $I^2O^4(NO)^2$.

When iodic anhydride is heated with 5 pts. of strong sulphuric acid, till a few bubbles of oxygen are given off, a scaly sulphur-yellow substance is formed, which appears to consist of $4I^2O^5.2IO^2.SO^4H^2$. If the boiling be continued, the evolution of oxygen goes on, and crystals are formed, having a much deeper yellow colour than the preceding, and apparently consisting of $2I^2O^5.IO^2.SO^4H$. Water decomposes both these compounds into sulphuric acid, iodic acid, and iodine. By continuing the action of the sulphuric acid till iodine begins to escape as well as oxygen, two other compounds are formed, to which Millon assigns the formulæ $2IO^2.2SO^3.H^2O$ and $I^{10}O^{19}.10SO^3.H^2O$. These substances, subjected to the action of moist air, appear to yield the compounds IO^2 and $I^{10}O^{19}$ in the free state. To the latter, Millon gives the name *sub-hypo-iodic acid [anhydride]*.

When sulphurous anhydride is allowed to act upon iodic anhydride longer than is required to form the compound $5I^2O^5.SO^3$ (p. 299), a large quantity of iodine is separated, and a lumpy adhesive mass is formed, which, if left for a day standing over water in a bell-jar, then washed with alcohol and with water, leaves an oxide of iodine containing I^6O^{13}, contaminated with a small quantity of sulphuric acid. It is a brown-yellow powder which does not decompose in the air, but absorbs a small quantity of water from it. Dilute nitric acid dissolves it, with separation of iodine; fuming nitric acid converts it into iodic acid. When heated to 100°, it splits up into iodine and iodic anhydride: $5I^6O^{13} = 13I^2O^5 + I^4$. Water decomposes it slowly at ordinary temperatures, quickly at 100°, into iodine and iodic acid.

Aqueous alkalis act in the same manner; but alcoholic alkalis do not act upon it at ordinary temperatures. This circumstance distinguishes it from the oxides IO^2 and $I^{10}O^{19}$ above-mentioned, which, according to Millon, form with alcoholic potash, brick-red easily decomposible salts. Absolute alcohol, ether, acetic ether, and sulphide of carbon are likewise without action on the oxide I^6O^{13}, even at the boiling heat. (Kämmerer, J. pr. Chem. lxxxiii. 72.)

Iodic acid, Anhydride and Salts.

Iodic Acid. HIO^3. (Gm. ii. 253.)—This acid is produced by the action of oxidising agents upon iodine in presence of water or alkalis. According to Pettenkofer (Jahresber. 1857, p. 581), it is sometimes found in commercial nitric acid (the iodine being doubtless derived from the Chili saltpetre used in the preparation). According to Riche (Compt. rend. xlvi. 348), it is produced by the electrolysis of aqueous hydriodic acid or aqueous iodine; in the former case, the hydriodic acid is simply oxidised to HIO^3 by oxygen evolved by the decomposition of the water; in the latter the iodine is first converted into hydriodic acid, which is then oxidised in the manner just mentioned. It is also produced by the action of iodine on chloric or bromic acid. (Kämmerer, J. pr. Chem. lxxxv. 452.)

Preparation.—1. Small quantities of iodic acid are conveniently prepared by heating iodine with the strongest nitric acid free from nitrous acid in a wide glass tube, and leaving the liquid to cool. Iodic acid is then deposited in crystals (Connel). Jacquelain (Ann. Ch. Phys. [3] xxx. 332) recommends this as the best mode of preparing iodic acid in all cases. He heats 5 grms. of dry iodine in a flask with 200 grms. nitric acid of specific gravity 1·5 to 60° for an hour; decants the supernatant liquids (the upper consisting of nitric acid containing pernitric oxide, the lower of a red-brown solution of iodine in nitric acid) from the separated iodic acid; distils these liquids down to one-sixth; and gently heats the residue, together with the crystallised iodic acid, in a vessel in which it is protected from dust; iodic anhydride then separates in nacreous crystals.—2. For preparing larger quantities, Liebig's method is, however, generally preferred. It consists in suspending an ounce or two of pulverised iodine in a pound of water, and passing a stream of chlorine through the liquid, till the iodine is completely dissolved:

$$6H^2O + 5Cl^2 + I^2 = 10HCl + 2HIO^3.$$

Digitized by Google

The brown strongly acid liquid is then slightly supersaturated with carbonate of sodium, whereby a considerable quantity of iodine is precipitated, which may be collected on a filter, then suspended in water, and treated with chlorine as before. The filtered solution contains iodate and chloride of sodium, with a trace of carbonate, which may be neutralised by hydrochloric acid. On afterwards adding chloride of barium to the filtered liquid as long as a precipitate is formed, the whole of the iodic acid is thrown down as iodate of barium, which may be collected on a filter, dried, and then decomposed by boiling it for half an hour with 2 pts. of oil of vitriol diluted with 10 or 12 pts. of water. The iodic acid thus liberated dissolves in the water, and the solution filtered from the sulphate of barium and evaporated at a gentle heat, yields the acid in the form of a crystalline mass. Kämmerer (J. pr. Chem. lxxix. 94) dissolves iodine in hot saturated baryta-water; filters the solution of iodide of barium from the separated iodate; passes chlorine through the filtrate (which at first precipitates iodine, but in a state of very fine division, so that it is very quickly oxidised), and thereby converts the whole of the iodide of barium into iodate, from which the iodic acid may then be separated by sulphuric acid.—3. Another very good method of preparing the acid is to digest 4 pts. of iodine with 7·5 pts. of chlorate of potassium in 40 pts. of water acidulated with 10 pts. of nitric acid, and heat the liquid sufficiently to cause rapid evolution of chlorine. In a short time the iodine is completely oxidised, and the iodic acid thus formed may be precipitated by baryta, and separated again by sulphuric acid. The largest crystals are obtained when the solution contains a slight excess of sulphuric acid.

The crystallised acid, HIO^3 or $I^2O^5.H^2O$, when exposed to a heat of 130°, or digested in absolute alcohol, is partly resolved into water and iodic anhydride, which remains combined with the iodic acid, forming the compound $I^2O^5.HIO^3$ or $3I^2O^5.H^2O$:

$$3HIO^3 = I^2O^5.HIO^3 + H^2O,$$

which at 170° suffers further decomposition, yielding water and iodic anhydride.

Iodic anhydride, I^2O^5, crystallises in forms belonging to the trimetric system, and often reduced to the tabular form by the predominance of two parallel faces ∞P. For P the ratio of the principal to the secondary axes is 1 : 0·7586 : 0·7122. Angles P : P in the terminal edges = 99° 22′, and 105° 12′; in the lateral edges = 125° 7′; ∞P : ∞P = 93° 37′. The pyramidal faces occur sphenoïdo-hemihedrally. Cleavage perfect parallel to P∞; imperfect parallel to P∞ (Schabus, *Bestimmung der Krystallgestalten in chemischen Laboratorien erzeugter Produkte*, Wien, 1855; Jahresber. 1854, p. 310). Specific gravity of the crystals = 4·250 (Filhol, Ann. Ch. Phys. [3] xi. 415). At the temperature of boiling olive-oil, the anhydride is completely resolved into iodine and oxygen. It dissolves in water, forming iodic acid.

Pulverised iodic anhydride is reduced at ordinary temperatures by a small quantity of *sulphurous anhydride*, yielding sulphuric anhydride and free iodine; by continued action of sulphurous anhydride at 100°, it is converted into a light yellow granulo-crystalline mass, consisting of an iodosulphuric anhydride, $5I^2O^5.SO^3$. This compound is quickly decomposed by contact with air and water, with separation of iodine. By absolute alcohol or ether, it is resolved into I^2O^5 and SO^3; and by alcoholic potash it is converted into iodate and sulphate of potassium. Strong sulphuric acid does not act upon it at common temperatures; hydrochloric acid dissolves it, with evolution of chlorine and formation of chloride of iodine. By still longer exposure to the action of sulphurous anhydride, the iodic anhydride is completely decomposed, yielding a large quantity of iodine, and an adhesive mass containing an oxide of iodine, I^6O^{13} (p. 298).

Nitro-iodic anhydride, $I^2O^4(NO)^2$?—Millon (Ann. Ch. Phys. [3] xii. 330), by triturating iodine with strong nitric acid, obtained a yellow powder which he regarded as a compound of nitric acid with periodic oxide, IO^3; it was resolved by water into nitric acid, iodic acid, and iodine, and when treated with dilute alcohol yielded a small quantity of periodic oxide, IO^2 (Millon's *hypo-iodic acid*). Kämmerer (J. pr. Chem. lxxxiii. 72) has obtained the same substance by Millon's method, also by treating iodine with a mixture of fuming nitric and strong sulphuric acids, and assigns to it the composition above given. He finds that it is decomposed by drying over lime, with evolution of nitric oxide, and that, when dried in an atmosphere of carbonic anhydride, it splits up into nitric oxide and periodic oxide. It is decomposed by water and by aqueous acids and alkalis; hydrochloric acid dissolves it, with evolution of chlorine and formation of chloride of iodine. Alcohol, ether, and acetic ether are violently attacked, often with incandescence, even by small quantities of the compound. By exposure to moist air at common temperatures, it is decomposed into iodine, iodic acid, and nitric acid; in dry and very cold air it remains unaltered for a long time. It dissolves slowly, and without decomposition, in strong sulphuric acid, and sometimes separates from the solution spontaneously, but is easily precipitated on scratching the sides of the vessel with a glass rod, or adding fuming nitric acid to the solution. The sulphuric acid solution, when boiled, gives off a large quantity of nitric oxide.

Digitized by Google

Iodic acid, HIO^3, crystallises from a strong aqueous solution in transparent six-sided tables without water of crystallisation (Serullas, Marignac). According to Rammelsberg (Pogg. Ann. xc. 12) the crystals are trimetric, the ratio of the brachydiagonal, macrodiagonal, and principal axis being = 0·58905 : 1 : 1·1903. They exhibit the faces ∞P, $\breve{P}\infty$, oP, with $\frac{1}{2}\breve{P}\infty$ and $2\breve{P}\infty$ subordinate. In the brachydiagonal principal section $\infty P : \infty P = 119° 0'$; $\breve{P}\infty : \breve{P}\infty = 80° 4'$. The crystals are transparent and have a vitreous lustre; they are generally either tabular by predominance of oP, or elongated in the direction of the brachydiagonal; cleavage distinct parallel to oP, less distinct parallel to ∞P. According to Marignac (Jahresber. 1856, p. 296. 1857, p. 124) iodic acid crystallises from aqueous solution at 50°—60° for the most part in the form determined by Schabus for the anhydride,* less abundantly in the form just described as determined by Rammelsberg. Marignac finds, however, different values for some of the angles, viz., $\infty P : \infty P$ in the brachydiagonal principal section = 114° 46'; $\breve{P}\infty : \breve{P}\infty$ in the same = 79° 38'. Kämmerer (J. pr. Chem. lxxxv. 452) has obtained a hydrate of iodic acid, $2HIO^3.9H^2O$, which crystallises at 17° in beautiful hexagonal tables.

Iodic acid is very soluble in *water*, slightly soluble in *alcohol*. The aqueous acid bleaches litmus paper after first reddening it. It is easily decomposed by *deoxidising agents*, yielding in the first instance hydriodic acid, which then, with the remaining iodic acid, forms water and free iodine:

$$HIO^3 + 5HI = 3H^2O + I^6.$$

Hence aqueous iodic acid, though it does not of itself impart a blue colour to starch, produces this colour immediately on the addition of hydriodic, sulphydric or sulphurous acid, stannous chloride, vegetable acids, or other deoxidising agents. In some cases however an excess of the reducing agent converts the free iodine into hydriodic acid and destroys the blue colour: thus with sulphurous acid:

$$\underset{\text{Sulphurous acid.}}{H^2SO^3} + I^2 + H^2O = 2HI + \underset{\text{Sulphuric acid.}}{H^2SO^4}.$$

Nitric oxide gas reduces aqueous iodic acid at ordinary temperatures (Kämmerer). The acid heated in sealed tubes with *sulphide of carbon* is reduced to hydriodic acid, in like manner iodate of potassium to iodide (Schlagdenhauffen, J. Pharm [3] xxxiv. 175). *Ferrous sulphate* does not of itself appear to reduce iodic acid, but on addition of caustic soda and subsequent supersaturation with sulphuric acid, iodine is set free. In this case, it may be supposed that the ferrous sulphate first separates iodine, which is taken up by the soda-ley, forming iodide and iodate of sodium, and that, on addition of sulphuric acid, iodic and hydriodic acids are set free, which act upon each other in the way above mentioned, yielding free iodine (Hempel, Ann. Ch. Pharm. cvii. 97). Aqueous iodic acid yields by *electrolysis*, oxygen at the positive, and iodine at the negative pole, the separation of the latter being due to the action of nascent hydrogen resulting from the decomposition of the water. According to Buff (Ann. Ch. Pharm. cx. 257), the iodic acid is resolved by the current into H and IO^3, which latter is decomposed by the water, yielding HIO^3 and free oxygen.

Iodates. Iodic acid is monobasic, like chloric and bromic acids, the general formula of its normal salts being

$$MIO^3 = \left.\begin{matrix} IO^2 \\ M \end{matrix}\right\} O \text{ or } M^2O.I^2O^5.$$

But there are likewise acid iodates, or more properly anhydro-iodates, which may be regarded as compounds of the normal iodates with one or more molecules of iodic anhydride: thus there are three iodates of potassium, having the following formulæ:

Normal iodate of potassium	$2KIO^3$ or $K^2O.I^2O^5$.
Di-iodate of potassium . . .	$2KIO^3.I^2O^5$ or $K^2O.2I^2O^5$.
Tri-iodate of potassium . . .	$2KIO^3.2I^2O^5$ or $K^2O.3^2IO^5$.

The normal iodates are obtained: 1. By bringing iodine in contact with an alkali and water, and removing the metallic iodide formed at the same time, by digestion in alcohol.—2. By direct mixture of iodic acid with a salifiable base.—3. By bringing the aqueous acid in contact with metals.

Most iodates are insoluble or sparingly soluble in water, the only easily soluble iodates being the ammonium-, potassium-, and sodium-salts. The solutions of these salts give with somewhat concentrated solutions of strontium- and calcium-salts, and with dilute solutions of barium-, lead-, and silver-salts, white crystalline, granular precipitates. The silver-precipitate is easily soluble in ammonia, very slightly soluble in nitric acid.

The normal iodates, when heated, either give up 3 atoms of oxygen, but no iodine, and are converted into metallic iodides (*e. g.* $KIO^3 - O^3 = KI$), or they part with their

* The crystals examined by Schabus probably consisted of the acid, not of the anhydride.

Digitized by Google

iodine and 5 atoms of oxygen, and are reduced to metallic oxides (*e.g.* $BaO.I^2O^5 - O^5 - I^2 = BaO$), accordingly as the metal has greater affinity for iodine or for oxygen. Some iodates detonate when heated with combustible bodies, *e.g.* on red-hot coals,—sometimes even when merely struck; but the detonation is much weaker than that produced by chlorates or nitrates. The aqueous solution of an iodate mixed with sulphurous acid yields iodine and sulphuric acid, part of which combines with the base (Gay-Lussac). With sulphydric acid, the solution of an iodate yields hydriodic acid, water, sulphur, and a sulphate (H. Rose); with hydriodic acid, or with a dissolved iodide mixed with an acid to liberate the hydriodic acid, it yields a metallic iodide, iodine, and water:

$$KIO^3 + 6HI = KI + I^6 + 3H^2O.$$

Iodides and iodates containing weak bases may also decompose one another in solution without the intervention of an acid, yielding an oxide and free iodine: thus with the zinc-salts:

$$Zn(IO^3)^2 + 5ZnI^2 = 6ZnO + I^{10}.$$

With hydrochloric acid, the iodates form water, a metallic chloride, trichloride of iodine, and free chlorine; and the metallic chloride thus produced often enters into combination with the trichloride of iodine (Filhol):

$$KIO^3 + 6HCl = 3H^2O + KCl + ICl^3 + Cl^2.$$

Arsenious acid, with the aid of heat, and likewise dichloride of tin, separate iodine from aqueous solutions of the iodates (Simon). Dilute sulphuric acid at a boiling heat separates the iodic acid from these salts (Gay-Lussac). When an aqueous solution of an iodate is heated with nitric acid, that acid at first takes hold of the base, either wholly or in part; but when the solution is evaporated to dryness and more strongly heated, the less volatile iodic acid drives out the nitric acid. (Penny, Ann. Pharm. xxxvii. 203.)

Iodates heated with strong hydrochloric acid and mercury, or with strong sulphuric acid and ferroso-ferric oxide, impart a blue colour to starch, in consequence of the liberation of iodine.

Iodate of Aluminium. A solution of moist hydrate of alumina in iodic acid evaporated to a syrup and then left over sulphuric acid, yields deliquescent crystals.

Iodate of Ammonium, $(NH^4)IO^3$, is produced by saturating caustic ammonia or carbonate of ammonium with iodic acid or chloride of iodine, and separates as a crystalline powder if the solutions are moderately concentrated. By spontaneous evaporation it is generally said to be obtained in small shining cubes. According to Marignac, however (Ann. Min. [5] ix. 1), the crystals are dimetric, exhibiting the combination $oP . \infty P\infty$, often with P, 2P, ∞P, $P\infty$ and $2P\infty$ subordinate. Angle $oP : P = 124° 54'$; $oP : 2P = 105° 14'$; $oP : P\infty = 134° 37'$; P : P in the terminal edges = 109·7°. That the crystals are not monometric, is also shown by the observation of Marbach (Jahresber. 1855, p. 145), that they act upon polarised light. It decomposes with a hissing noise at 150°, giving off equal volumes of oxygen and nitrogen together with iodine and water. It detonates on glowing coals, and is decomposed by hydrochloric acid, yielding a compound of sal-ammoniac and trichloride of iodine, together with water and free chlorine (Filhol). It dissolves in 38·5 pts. of cold water at 15°, and in 6·9 pts. of boiling water. (Rammelsberg.)

Iodate of Barium, $Ba(IO^3)^2.H^2O$.—This salt is precipitated when iodine is dissolved in baryta-water, iodide of barium remaining in solution. It may also be prepared by saturating an aqueous solution of trichloride of iodine with carbonate of barium or baryta-water, or by precipitating a concentrated solution of chloride of barium with iodate of sodium. The hydrated salt forms a granular powder. From a solution in hot nitric acid, however, it is deposited on cooling or on addition of ammonia, in small crystals (Rammelsberg), which, according to Marignac (*loc. cit.*), are monoclinic and isomorphous with bromate and chlorate of barium, exhibiting the combination $\infty P . (P\infty) . -P\infty$. Angle $\infty P : \infty P$ in the clinodiagonal principal section = 82° 0'; $(P\infty) : (P\infty)$ in the same = 76° 42'; $-P\infty : \infty P = 119° 4'$. The water of crystallisation escapes at a temperature below 200°. On heating the salt more strongly in a porcelain retort, vapour of iodine and oxygen gas are evolved, and a residue is obtained, consisting of basic periodate of barium (Rammelsberg):

$$5Ba(IO^3)^2 = Ba(IO^4)^2.4BaO + 8I + O^{16}.$$

It does not detonate on ignited charcoal, but sometimes exhibits phosphorescence (Gay-Lussac). Hydrochloric acid dissolves it readily, even in the cold, the liquid assuming a dark-yellow colour (probably arising from the formation of a double chloride of iodine and barium) and evolving chlorine. It dissolves with difficulty in warm nitric acid (Rammelsberg). It is soluble in 3,333 pts. of water at 18°, in 625 pts.

Digitized by Google

of boiling water (Gay-Lussac), in 1,746 pts. of water at 15°, and in 600 pts. of boiling water (Rammelsberg); the anhydrous salt dissolves in 3,018 pts. water at 13·5°, and in 661 pts. boiling water. (Kremers, Pogg. Ann. xciv. 255.)

Iodate of Bismuth, $2\dot{B}\ddot{i}I^3O^9.H^2O$.—Iodate of sodium added in excess to a solution of bismuth which is no longer precipitated by water, throws down the whole of the bismuth as iodate. The precipitate is nearly insoluble in nitric acid. When ignited it leaves trioxide of bismuth mixed with iodide.

Iodate of Calcium, $Ca(IO^3)^2.5H^2O$.—Crystallises slowly from the mixed solutions of iodate of potassium and chloride of calcium in water (Pleischl), a large proportion of the salt, however, remaining dissolved (Rammelsberg). The crystals are rendered anhydrous by heat. The dry salt gently ignited in a porcelain retort evolves 14·785 per cent. of oxygen and 54·072 of iodine, leaving a residue amounting to 31·143 per cent., and consisting chiefly of pentabasic periodate of calcium; but when heated more strongly, it evolves a still larger amount of oxygen (in the whole 17·176 per cent.) and of iodine (in the whole 62·478 per cent.), and leaves 20·346 per cent. of a mixture of pentabasic periodate and much free lime, which may be separated by water (Rammelsberg, Pogg. Ann. xliv. 576). Iodate of calcium detonates violently on ignited charcoal (Gay-Lussac). When treated with concentrated hydrochloric acid, by which it is readily dissolved, it yields an orange-coloured liquid, smelling of trichloride of iodine, and similar to that yielded by iodate of potassium; it does not, however, give crystals of the double chloride of iodine and calcium (Filhol). The hydrated salt forms four-sided prisms, which effloresce in the air, with partial loss of water, and become anhydrous at a temperature below 200° (Rammelsberg). From a solution acidulated with nitric acid, it separates in trimetric crystals, $\infty P . \infty\breve{P}\infty . 3P . P . oP . 3\breve{P}\infty . 4\breve{P}\infty$. Ratio of axes, $a : b : c = 0{\cdot}4537 : 1 : 0{\cdot}5231$. $\infty P : \infty P$ in the brachydiagonal = 132° 55′; $oP : P = 127° 22'$; $oP : 3P = 104° 17'$ (Senarmont, Marignac, Jahresber. 1857, p. 125). The crystals dissolve in 454 pts. of water at 18°, and in 102 pts. of boiling water (Gay-Lussac); in 253 pts. at 15°, in 75 pts. of boiling water, and much more copiously in nitric acid. From the latter solution the salt is precipitated by ammonia in prisms (Rammelsberg). Alcohol separates the salt from an aqueous solution. (O. Henry.)

Iodate of Cerium, $Ce(IO^3)^2.H^2O$, is a white precipitate which gives off its water at 200°, and leaves pure ceric oxide when ignited.

Iodate of Cobalt, $Co(IO^3)^2.H^2O$, is obtained by dissolving recently precipitated carbonate of cobalt in hot aqueous iodic acid, and separates partly on cooling, partly by evaporation, in violet-red crystalline crusts. Dissolves in 148 pts. of cold and 90 pts. of hot water. Gives off its water of crystallisation at 200°. At a red heat, it gives off iodine and oxygen and leaves cobaltoso-cobaltic oxide, Co^3O^4. Alcohol added to a solution of this salt in sal-ammoniac, throws down a pale-red double salt.

Iodate of Copper.—Iodate of sodium forms with sulphate of copper (after some time only if the solutions are dilute) a greenish-blue precipitate, consisting of $2Cu(IO^3)^2.3H^2O$, which gives off its water at 200° (Rammelsberg). According to Millon, iodic acid forms, even in very dilute solutions of copper-salts, a blue crystalline precipitate composed of $Cu(IO^3)^2.H^2O$, and the same compound is obtained by digesting recently precipitated hydrate or carbonate of copper with iodic acid at ordinary temperatures. When hydrated cupric oxide is washed with boiling water and covered with a sufficient quantity of solution of iodic acid, an olive-coloured powder is obtained which has the same composition as the blue crystals, but requires a temperature about 40° higher to dehydrate it completely. Ignited cupric oxide shaken up with aqueous iodic acid, forms a basic salt, $3[Cu(IO^3)^2.CuO].H^2O$, which however is converted into the olive-coloured salt when the mixture is boiled.

Iodates of Iron.—Ferric Iodate, $Fe^2O^3.2I^2O^5.8H^2O$ or $2Fe^2(IO^3)^6.Fe^2O^3.24H^2O$, is a yellowish-white precipitate obtained by adding iodate of sodium to ammonio-ferric sulphate. The precipitate when dry becomes heavier and assumes a reddish tint. It is soluble in nitric acid, and leaves pure ferric oxide when ignited.

Ferrous Iodate is produced on mixing ferrous sulphate with iodate of potassium, as a white precipitate, which dissolves readily in excess of the ferrous sulphate, but quickly turns brown and decomposes, with evolution of iodine, especially when heated. The brown precipitate dissolves in hydrochloric acid, with evolution of chlorine, and ammonia throws down from the solution a mixture of ferric hydrate and iodide of nitrogen.

Iodate of Lanthanum, $La(IO^3)^2.H^2O$.—Precipitated as a crystalline powder on adding sulphate of lanthanum to aqueous iodic acid. From solution in hot water, it separates on evaporation in white crystalline scales. Gives off its water at a temperature above 110°. (Holzmann, J. pr. Chem. lxxv. 321; Hermann, *ibid.* lxxxii. 385.)

Iodate of Lead, $Pb(IO^3)^2$.—White precipitate, very sparingly soluble in water and

Digitized by Google

in nitric acid. Gives off iodine and oxygen when heated, and leaves a mixture of oxide and iodide of lead, from which the oxide is easily dissolved out by acetic acid.

Iodate of Lithium, $LiIO^3$.—Crystalline crusts, soluble in 2 pts. of water.

Iodate of Magnesium, $Mg(IO^3)^2.4H^2O$.—Shining crystals soluble in 3 pts. of boiling and 9·43 pts. of cold water. They are monoclinic, exhibiting the combination, ∞P . $\infty P\infty$. $+P$. $-P$. oP . $-\frac{1}{2}P\infty$. In the clinodiagonal principal section, ∞P : $\infty P = 78° 20'$; $+P$: $+P = 91° 53'$; $-P$: $-P = 120° 30'$; further, oP : $\infty P\infty = 100° 40'$; oP : $-\frac{1}{2}P\infty = 155° 32'$. The crystals cleave very distinctly parallel to $\infty P\infty$ (Marignac, Jahresber. 1857, p. 125). When heated they quickly become opaque and give off water, becoming completely anhydrous at 240° (Millon). At a red heat, the salt suffers decomposition and leaves pure magnesia.

Iodate of Manganese, $Mn(IO^3)^2$, is best obtained by precipitating a concentrated solution of acetate of manganese with iodate of sodium. It is pale red, soluble in 200 pts. of water, and when ignited leaves pure manganoso-manganic oxide. According to Berzelius, it contains 1 at. water $[Mn(IO^3)^2.H^2O]$.

Iodates of Mercury.—1. *Mercuric Iodate.* Produced by digesting recently precipitated mercuric oxide in iodic acid. It is a white anhydrous powder, insoluble in water, but dissolving easily in hydrochloric acid, with evolution of chlorine. The solution mixed with stannous chloride yields a red precipitate of mercuric iodide, which by the further action of the tin-salt is reduced to yellow mercuroso-mercuric iodide. Mercuric iodate when heated gives off oxygen and is converted into iodide.

2. *Mercurous Iodate*, $Hg^2(IO^3)^2$.—A solution of mercurous nitrate rendered as neutral as possible, yields with iodate of sodium a white precipitate, which is dissolved by hydrochloric acid, with evolution of chlorine, and yields a solution from which ammonia throws down iodide of nitrogen. It dissolves with difficulty in nitric acid, and is completely volatilised by heat, being at the same time resolved into mercuric iodide, mercury and oxygen.

Iodate of Nickel, $Ni(IO^3)^2.H^2O$.—Obtained by dissolving recently precipitated hydrate of nickel in iodic acid, or by evaporating to dryness a solution of 1 pt. sulphate of nickel and 1½ pt. iodate of sodium, and dissolving out the sulphate of sodium from the residue with water. From a hot-saturated solution, it separates as a light-green crystalline powder. It dissolves in 77½ pts. of boiling and 120⅝ pts. of cold water. When ignited, it leaves pure oxide of nickel. Ammonia dissolves it readily, forming a blue liquid, from which alcohol throws down blue crystals, or a crystalline powder, consisting of *iodate of nickel-diammonium*, $Ni(IO^3)^2.4NH^3 = I^2O^6.N^2\left\{\begin{matrix}N^2H^6Ni''\\ .\ H^6\end{matrix}\right.$.

Iodates of Potassium.—1. *Mono-iodate or Normal Iodate.* This salt is prepared: 1. By adding iodine to solution of potash till a brown colour is produced, evaporating to dryness, and dissolving out the iodide of potassium formed at the same time with alcohol of specific gravity 0·81:

$$6KHO + I^6 = KIO^3 + 5KI + 3H^2O.$$

Should the iodate thus obtained contain carbonate of potassium, the latter must be decomposed by acetic acid, the whole evaporated, and the acetate of potassium removed by alcohol.

2. By dissolving trichloride of iodine in potash, the products being iodate, iodide and chloride of potassium:

$$12KHO + 3ICl^3 = 2KIO^3 + 9KCl + KI + 6H^2O.$$

The iodide and chloride are dissolved out by alcohol, as in the former process, but the latter, being less soluble, is more difficult to remove.

3. By melting iodide of potassium in a crucible, leaving it to cool till it becomes semifluid, and then gradually adding 1½ pts. chlorate of potassium. The mass becomes fluid, swells up, and solidifies to a spongy mass of iodate and chloride of potassium. It is dissolved in hot water, the iodate left to crystallise, the crystals redissolved in hot water and the iodate precipitated by alcohol.

Mono-iodate of potassium forms small white cubic crystals (Gay-Lussac); $\infty O\infty$. ∞O (Marignac), but it is not easy to obtain distinct crystals. Specific gravity 3·979 (water at 17·5° = 1) (Kremers). It dissolves in 13 pts. water at 14° (Gay-Lussac); in 19·02 pts. water at 0·5°, in 14·85 pts. at 9·4°, in 10·77 pts. at 22·2°, in 5·95 pts. at 45·8°, and in 3·67 pts. at 69·2°. An aqueous solution of specific gravity 1·0741 at 19·5° contains 9·08 pts. KIO^3, for every 100 pts. water. The saturated aqueous solution boils at 102° (Kremers, Pogg. Ann. xciv. 271; xcv. 121; xcvii. 5). More soluble in aqueous iodide of potassium than in water. Insoluble in alcohol of specific gravity 0·81. Soluble in warm sulphuric acid without decomposition of the iodic acid. (Berzelius.)

At a low red heat, the salt melts and froths up, and is converted, with loss of

Digitized by Google

22·59 per cent. oxygen into iodide of potassium (Gay-Lussac). If only part of the oxygen is expelled, the residue consists of iodide and iodate, without any periodate (Rammelsberg). It deflagrates with a purple light on glowing charcoal.

The aqueous solution exhibits with sulphydric acid and other reducing agents, the reactions already described for iodates in general (p. 301). From a solution of the salt mixed with iodide of potassium, the stronger acids precipitate iodine. With strong hydrochloric acid, it yields water, free chlorine, and chloride of iodine and potassium:

$$KIO^3 + 6HCl = 3H^2O + Cl^2 + KICl^4.$$

A solution of iodate of potassium in excess of boiling nitric acid yields crystals of iodic acid on cooling, while nitre remains in solution; if however it is evaporated to dryness, one half the nitre formed is decomposed, and there remains a mixture of 1 atom of nitrate and 1 atom of di-iodate of potassium. When greater heat is applied, all the nitric acid is decomposed into pernitric oxide and oxygen, and driven off, so that the residue consists merely of iodate of potassium. (Penny, Ann. Ch. Pharm. xxxvii. 203.)

Double-salt of Iodate and Acid Sulphate of Potassium, $KIO^3.KHSO^4$.—This salt separates after the tri-iodate (p. 305) from a solution of the mono-iodate mixed with sulphuric acid. It was first obtained by Serullas (Ann. Ch. Phys. [2] xliii. 113), who regarded it as a compound of the di-iodate with anhydrous di-sulphate of potassium. Millon (Ann. Ch. Phys. [3] ix. 497) supposed it to be a compound of mono-iodate and monosulphate of potassium, $2KIO^3.K^2SO^4$. The formula above given was determined by Marignac (Ann. Min. [5] ix. 1), who obtained it of the same composition, even when the proportions between the sulphuric acid, iodic acid and potash in the solution were varied. The crystals are monoclinic, exhibiting the combination $\infty P.\infty P2.\infty P3.\infty P\infty.oP.-P.-P2.-P\infty.+P\infty$ (predominating at the ends) $+3P\infty.(P\infty).(\frac{1}{2}P\infty)$. Angle $\infty P:\infty P$ in the clinodiagonal principal section = 54° 53′; $\infty P2:\infty P2$ in the same = 92° 10′; $oP:\infty P = 91° 29'$; $oP:\infty P\infty = 93° 14'$; $\infty P\infty:+P\infty = 115° 50'$; $\infty P\infty:-P\infty = 120° 42'$ (Marignac). When heated to redness, they give off oxygen and iodine and leave sulphate and iodide of potassium.

Di-iodate, $2KIO^3.I^2O^5$ or $K^2O.2I^2O^5$.—Obtained—1. By mixing the aqueous solution of the mono-iodate with hydrochloric acid, and precipitating with alcohol.—2. By partially saturating an aqueous solution of trichloride of iodine with caustic potash or carbonate of potassium, whereupon the mixture becomes heated, and on cooling deposits a compound of the di-iodate with chloride of potassium (the mother-liquor saturated with potash still yields the mono-iodate). The solution of this compound, largely diluted with water, and evaporated in the air at 25°, yields the di-iodate in beautiful transparent right rhombic prisms, with dihedral summits, having a sour, astringent taste, and acid reaction.

According to Marignac (Jahresb. 1856, p. 297), the crystals contain $K^2O.2I^2O^5.H^2O$, and exhibit three essentially different forms, one trimetric, the other two monoclinic, the occurrence of which is independent of the temperature of crystallisation. The trimetric crystals, which separate only from solutions containing a small quantity of the mono-iodate, exhibit chiefly the combination $\infty P.\infty\breve{P}\infty.\infty\bar{P}\infty.oP.\frac{1}{2}P.\frac{1}{3}\breve{P}\infty.\frac{1}{4}\bar{P}\infty$. Angle $\infty P:\infty P = 82° 10'$; P: P in the macrodiagonal principal section = 87° 10′; in the brachydiagonal = 101° 40′; $oP: P = 106° 4'$; $oP:\frac{1}{3}\breve{P}\infty = 127° 23'$; $oP:\frac{1}{4}\bar{P}\infty = 146° 48'$. No cleavage. According to Schabus (Jahresber. 1854, p. 310), the combination is oP (predominant) . $P.\frac{2}{3}P.\breve{P}\infty.\frac{1}{3}\breve{P}\infty.\infty P.\infty\breve{P}\infty.\infty\bar{P}\infty$. For P, the ratio of principal and secondary axes is 1 : 0·8973 : 0·7819. Angles P : P in the the terminal edges = 111° 13′ and 121° 2′; in the lateral edges = 97° 2′; $\infty P:\infty P = 82° 4'$. Cleavage imperfect parallel to oP.—The second form, which is monoclinic, separates, according to Marignac, chiefly from solutions containing a slight excess of acid. According to Schabus, the predominant combination is $\infty P2.\infty P\infty.oP.+P.-P$. The principal axis, clino- and ortho-diagonals, are in the proportion 1 : 1·7307 : 0·8627. Angle of the inclined axes = 87° 16′. $\infty P2:\infty P2$ in the clinodiagonal principal section = 78° 48′; $oP:-P = 129° 22'$; $oP:+P = 128° 9'$. The crystals are often joined as twins, the face of combination being apparently parallel to $+\frac{1}{4}P\infty$. Marignac has also measured these crystals, viewing them in a different direction, so that the faces oP, $\infty P\infty$, $\infty P2$, &c. in the preceding determination, become respectively $\infty P\infty$, oP, $(\frac{1}{2}P\infty)$, &c. in that of Marignac. Regarded thus, the crystals exhibit the faces $oP.\infty P\infty.\infty P2.-P.(P\infty).(\frac{1}{2}P\infty)$, with several subordinate clinodiagonal domes and hemipyramids. $\infty P2:\infty P2$ in the clinodiagonal principal section = 120° 17′; $-P:-P$ in the same = 87° 48′; $oP:(P\infty) = 110° 53'$; $oP:(\frac{1}{2}P\infty) = 127° 20'$; $oP:\infty P\infty = 91° 56'$. The crystals are almost always intersecting twins, with the face of combination $-P\infty$; rarely contact-twins joined by the face oP. Cleavage parallel to oP.—The third form, which accompanies the other two, is also monoclinic,

inclined to one another at an angle of 127½°, and
of the prism, extending in a direction parallel to
passed into the solution of the salt in ammonia,
throws down iodide of silver. Hydrochloric acid
de of silver, chloride of iodine, and free chlorine.
o-iodate, $NaIO^3$ or $Na^2O.I^2O^5$, is obtained: 1. By
rough 10 pts. of water containing 1 pt. of iodine
liquid with carbonate of sodium; passing chlorine
the iodine thus thrown down; again neutralising
iodine thus separated by means of chlorine, and
ed to $\frac{1}{10}$th its bulk, mixed, while still warm, with
ompact crystalline mass, consisting of eight-sided
d from adhering chloride of sodium by washing
iv. 362). An excess of carbonate of sodium must
date of sodium will be formed (Magnus and
uflos (Schw. J. lxii. 390), the addition of alcohol
date can be separated from the chloride of sodium

Digitized by Google

by crystallisation.—2. By partially saturating aqueous trichloride of iodine with caustic soda or carbonate of sodium, precipitating with alcohol, washing the precipitate with the same liquid, and recrystallising from hot water. (Serullas.)

Mono-iodate of sodium separates from an aqueous solution left to evaporate in moderately warm air (Rammelsberg), or from a hot concentrated solution on cooling (Penny), in crystals containing 1 at. water: $NaIO^3.H^2O$. This hydrate forms tufts of fine silky needles, which, if the temperature falls below 5°, while they are still immersed in the liquid, are converted into the pentahydrated crystals. They give off all their water at 180° (Rammelsberg, Penny). The pentahydrated salt, $NaIO^3.5H^2O$, obtained by spontaneous evaporation below 5°, forms octagonal prisms of the trimetric system, with pyramidal summits, the combination being $\infty\breve{P}\infty . \infty\breve{P}\infty . P$, with $\breve{P}\infty$ subordinate. Axes $a : b : c = 0{\cdot}9534 : 1 : 0{\cdot}6607$ (ii. 144). Angles P : P in the terminal edges = 119° 56′ and 123° 30′; in the lateral edges = 87° 30′; $\infty P : \infty P = 92° 45'$ and 87° 15′. The crystals are prismatically elongated in the direction of the principal axis, the faces ∞P being almost always unequally developed. When exposed to the air, they give off 4 at. water and are converted into the monohydrated salt (Rammelsberg, Pogg. Ann. xliv. 548; xc. 12). According to Millon (Ann. Ch. Phys. [3] ix. 400), crystals containing 2, 3, 6, and 8 at. water are also obtained, under special circumstances. Penny (Ann. Ch. Pharm. xxxvii. 203), by cooling a somewhat dilute solution, obtained crystals containing $NaIO^3.3H^2O$.

The anhydrous salt, obtained by drying the crystals at 150°, dissolves in 13·8 pts. of water at 14·5°, but is insoluble in alcohol (Gay-Lussac). According to Kremers (Pogg. Ann. xcvii. 5, 8), it dissolves in 39·75 pts. water at 0°, in 11·03 pts. at 20°, in 6·95 pts. at 40°, in 4·79 pts. at 60°, in 3·61 pts. at 80°, and in 2·95 pts. at 100°. The saturated solution boils at 102°. A solution of specific gravity 1·0698 at 19·5° contains 8·13 pts. of the anhydrous salt for every 100 pts. of water. (Kremers, Pogg. Ann. xcix. 444.)

Mono-iodate of sodium melts when heated, and while still below redness, gives off 24·45 per cent. oxygen, together with iodine, leaving a mixture of iodide of sodium and soda (Gay-Lussac). According to Liebig, it leaves a hypo-iodite of sodium, containing $2Na^2O.I^2O$ or $Na^4I^2O^3$; when heated to redness, it yields 24·21 per cent. of oxygen, and 75·79 of iodide of sodium (Benckiser). It detonates on glowing charcoal, and slightly when mixed with sulphur and struck (Gay-Lussac). It is decomposed by concentrated hydrochloric acid into water, chlorine, and a yellow liquid, which probably contains trichloride of iodine and sodium, $NaCl.ICl^3$, but does not yield this compound in a crystalline form (Filhol, J. Pharm. xxv. 440). Heated with a little nitric acid, it yields di-iodate, and with a larger proportion, tri-iodate of sodium in the anhydrous state (Penny). When dissolved hot in a mixture of equal quantities of sulphuric acid and water, it gives, by evaporation, crystals which, when placed on bibulous paper and nearly dry, become all at once fluid and tenacious. (Liebig.)

Double Salts of Mono-iodate of Sodium.—1. With *bromide of sodium*, $2NaBr.NaIO^3.9H^2O$. —Obtained by dissolving the iodate in a hot strong solution of bromide of sodium. It crystallises, by cooling or spontaneous evaporation, in aggregations of extremely fine, colourless, transparent, six-sided laminæ, apparently rhombohedral combinations. It is easily soluble in water. When heated, it gives off a large quantity of water, melts, gives off oxygen mixed with iodine, and leaves a mixture of bromide and iodide of sodium. Two-thirds of the water is given off over sulphuric acid. (Rammelsberg, J. pr. Chem. lxxxv. 436; Rép. Chim. pure, 1862, p. 251.)

2. *With Chloride of Sodium*, $3NaCl.2NaIO^3.9H^2O$.—(1.) When chlorine is passed through a solution of iodate of sodium mixed with a rather large quantity of caustic soda as long as basic periodate of sodium (p. 310) continues to separate, the decanted liquid, when left at rest, deposits crystals of chloride of sodium, first combined with iodate of sodium, then by itself, and afterwards mixed with chlorate of sodium.—(2.) The mother-liquor obtained in the second mode of preparing mono-iodate of sodium (see above) deposits, at a higher temperature and greater degree of concentration, crystals of the compound of iodate and chloride. The crystals, which are large, colourless, and often transparent, belong to the triclinic system, and are sometimes triclinic pyramids having all their edges and summits truncated, frequently, also, modified by various pyramidal faces. They also form twins joined by the basal end-faces, and giving the crystal a tabular character. The axes *a*, *b*, *c* of the pyramid (*c* being the principal axis) are to one another as 1·1309 : 1 : 1·10436. The inclinations of the principal sections are by direct measurement, $\infty\breve{P}\infty : \infty\breve{P}\infty = 97° 16'$; $oP : \infty\breve{P}\infty = 104° 0'$; $oP : \infty\breve{P}\infty = 100° 63'$. Inclinations of the axes, by calculation, $b : c = 102° 57'$; $a : c = 99° 9'$; $a : b = 94° 56'$. The crystals are not efflorescent, but when heated, they give off their water, and melt to a clear liquid which gives off nothing but oxygen gas, and when very strongly heated, leaves a mixture of iodide and chloride of sodium. Water extracts the chloride of sodium, leaving the iodate with 1 at. water. (Rammelsberg, Pogg. Ann. xliv. 548: cxv. 584.)

Digitized by Google

3. *With Iodide of Sodium*, $NaI.NaIO^3.10H^2O$ (Mitscherlich); $3NaI.2NaIO^4.19H^2O$ (Penny); $3NaI.2NaIO^3.20H^2O$ (Marignac).—This compound, discovered by Mitscherlich (Pogg. Ann. xi. 162; xvii. 481), is obtained by dissolving iodine in a cold and not very concentrated aqueous solution of caustic soda (or the carbonate, according to Penny) till it begins to turn brown, then leaving it in a cold place till it crystallises. Prisms of pure iodate of sodium then first appear, but afterwards redissolve, and are replaced by this compound (Mitscherlich). The same crystals are produced in a few days by immersing crystals of iodate of sodium in a strong solution of the iodide, and leaving the liquid to itself at a temperature not above 15° (Penny, Ann. Ch. Pharm. xxxvii. 202). The crystals are hexagonal tables, oR . ∞R, with + R, − ½R and other faces. Angle oR : R = 115° 7′; oR : − ½R = 133° 10′ (Marignac, Jahresb. 1857, p. 124). When heated they first give off water, then oxygen, with a trace of iodine. Cold water dissolves them without decomposition, but alcohol dissolves the iodide of sodium, leaving the iodate.

Acid Iodates of Sodium.—When an aqueous solution of trichloride of iodine is mixed, first with mono-iodate of sodium, then with alcohol, the di-iodate separates out, but this salt, if dissolved in water and evaporated, yields crystals of the mono-iodate, and an acid mother-liquor (Serullas, Ann. Ch. Phys. xlv. 59). By evaporating also a mixture of the iodate with excess of iodic acid, the neutral salt crystallises out first, and then the iodic acid (Rammelsberg). Penny obtained a di-acid and tri-acid salt, by treating the mono-iodate with nitric acid.

Iodate of Tin.—Iodate of sodium forms, with dichloride of tin, a precipitate which is white at first, but soon turns yellow, brown and grey, yielding tetrachloride and di-oxide of tin and free iodine.

Iodates of Uranium.—The *uranic salt*, $U^2O^3.I^2O^5.5H^2O$ or $(U^2O^2)''(IO^3)^2.5H^2O$, is obtained, by double decomposition, as a yellow precipitate which dissolves with difficulty in nitric acid, leaves uranoso-uranic oxide when ignited, and is decomposed by potash. *Uranous iodate* is obtained by precipitation from uranous chloride, as a greyish-green substance, which soon decomposes, being partially converted into the uranic salt.

Iodate of Yttrium.—Precipitable from concentrated solutions; remains as a crystalline crust on evaporation. It is anhydrous, dissolves in 160 pts. water, and when suddenly heated, decomposes with explosion and deflagration.

Iodate of Zinc, $Zn(IO^3)^2.2H^2O$.—To prepare this salt, a solution of sulphate of zinc and iodate of sodium in equivalent proportions is evaporated to dryness, and the resulting sulphate of sodium is dissolved out by water. Iodate of zinc then remains as a white powder, soluble in 75·9 pts. of hot, and 113·8 pts. of cold water, soluble also in nitric acid and in ammonia. The ammoniacal solution yields by spontaneous evaporation, or on addition of alcohol, a crystalline salt consisting of $3Zn(IO^3)^2.8NH^3$ or $3(N^2H^6Zn)(IO^3)^2.2NH^3$. It is decomposed by water, with separation of oxide of zinc.

Iodate of zinc leaves oxide of zinc when ignited.

Periodic Acid, Anhydride and Salts.

Periodic or **Hyperiodic acid.** HIO^4 or $H^2O.I^2O^7$, or according to Langlois, H^3IO^5 or $5H^2O.I^2O^7$. (Magnus and Ammermüller, Pogg. Ann. xxviii. 514.—Benckiser, Ann. Ch. Pharm. xvii. 254.—Langlois, Ann. Ch. Phys. [3] xxxiv. 257; Jahresb. 1852, p. 345.)—This acid, which was discovered by Magnus and Ammermüller (Pogg. Ann. xxviii. 514), is produced, in the form of a disodic salt, by the action of chlorine on a solution of iodate of sodium mixed with carbonate of sodium or caustic soda:

$$\underset{\text{Sodic iodate.}}{NaIO^3} + 3NaHO + Cl^2 = \underset{\text{Disodic periodate.}}{Na^2H^3IO^6} + 2NaCl.$$

A good method of preparing it is to add 1 pt. of iodine to a solution of 7 pts. carbonate of sodium in 100 pts. water, and pass chlorine into the heated liquid as long as a precipitate continues to form. This precipitate, which consists of disodic periodate, is dissolved in nitric acid perfectly free from nitrous acid; nitrate of silver is then added; the resulting yellow precipitate of diargentic periodate is dissolved in hot dilute nitric acid; and the solution is concentrated at a moderate heat, till the monargentic periodate, $AgIO^4$, crystallises out; this salt, separated from the mother-liquor, is treated with cold water, which extracts half the periodic acid, reproducing the diargentic periodate; and the filtered solution is evaporated: pure periodic acid then crystallises out (Magnus and Ammermüller). Another method is to precipitate the solution of the disodic salt in nitric acid with nitrate of lead, decompose the precipitate of per-

Digitized by Google

iodate of lead with somewhat less than an equivalent quantity of dilute sulphuric acid, and concentrate the filtrate by evaporation (Benckiser). According to Langlois, however, the acid thus obtained is always contaminated with iodic acid.

The acid may likewise be obtained by igniting iodate of barium, which then gives off iodine and oxygen, and is converted into pentabasic periodate of barium—and decomposing that salt with sulphuric acid. But this method is not advantageous, because a considerable portion of the iodic acid is completely resolved by the heat into iodine and oxygen.

The iodates of the alkali-metals give off the whole of their oxygen when heated, and are converted into iodides; consequently periodic acid cannot be prepared in the same manner as perchloric acid (i. 910).

Periodic acid separates from its aqueous solution by evaporation, at a gentle heat, in colourless crystals, apparently having the form of oblique rhombic prisms, which deliquesce quickly in moist air, melt at 130°, and at 160° give off their water, leaving a white mass of periodic anhydride, I^2O^7, which, at 180° or 190°, gives off oxygen with great rapidity, leaving iodic anhydride (Benckiser). The crystals are rhombic prisms, having the composition $H^5IO^6 = HIO^4.2H^2O$ or $5H^2O.I^2O^7$. They melt at 130°, and between 200° and 210°, give off 5 at. water and 2 at. oxygen, and are reduced to iodic anhydride, I^2O^5, which at a higher temperature is completely resolved into iodine and oxygen. (Langlois.)

Periodic acid dissolves very easily in *water*, sparingly in *alcohol* and in *ether*, in which solutions it is slowly reduced to iodic acid. It is likewise reduced by many other *organic substances*, and instantly by *hydrochloric*, *sulphurous*, or *sulphydric acid*. With hydrochloric acid it forms water, chloride of iodine, and free chlorine. *Sulphur* is not oxidised by it; but *phosphorus* is partly converted into phosphoric acid—for the most part, however, into oxide of phosphorus. *Metals* are oxidised by the solution, forming basic periodates. It forms a precipitate with *tannic acid*, a reaction which distinguishes it from iodic acid. The precipitate dissolves in potash and in ammonia, with dark red colour, arising from the oxidation of the tannic acid, the iodine at the same time uniting with the alkali-metal. (Langlois.)

Periodates.—Periodic acid is generally regarded as monobasic, like perchloric acid, the formula of its normal salts being MIO^4 or $M^2O.I^2O^7$. Only four of these anhydrous monometallic periodates are however known, namely those of ammonium, potassium, sodium, and silver. All other periodates contain a larger proportion of base, and may be derived from the crystallised acid H^5IO^6, regarded as $HIO^4.2H^2O$, by the replacement of the water of crystallisation by a metallic oxide or hydrate, thus:

HIO^4	.	H^2O	. H^2O . .	Periodic acid.
$(NH^4)IO^4$	.	H^2O	. H^2O . .	Mono-ammonic periodate.
$NaIO^4$	.	NaHO.	H^2O . .	Disodic periodate.
$PbIO^4$	.	Pb^2O .	H^2O . .	Triplumbic periodate.
$CuIO^4$	.	Cu^2O .	CuHO. .	Tetracupric periodate.
$BaIO^4$	.	Ba^2O .	Ba^2O . .	Pentabarytic periodate.

The existence of the monohydric acid HIO^4 must however for the present be regarded as hypothetical, the only hydrate whose constitution has been established by analysis being the pentahydric acid, H^5IO^6, analysed by Langlois; and from this, regarded as a pentatomic molecule, $\left.\begin{matrix}(IO)^{vii}\\ H^5\end{matrix}\right\}O^5$, the greater number of the periodates may be derived by the partial or total replacement of the hydrogen by metals. The anhydrous periodates of potassium, silver, and sodium, (MIO^4) may then be regarded as metaperiodates, bearing to the orthoperiodates, M^5IO^6, a relation similar to that of metaphosphoric to orthophosphoric acid. There are a few periodates which cannot be included in either of the preceding formulæ, viz. a barium-salt containing $5BaO.2I^2O^7$ or $3BaO.2BaI^2O^8$, a potassium-salt containing $2K^2O.I^2O^7$ or $K^2O.2KIO^4$, and a silver-salt containing $2Ag^2O.H^2O.I^2O^7$ or $Ag^2O.HIO^4$.

The monometallic periodates are resolved by heat into oxygen and metallic iodide; the polymetallic salts into a mixture of iodide and oxide or reduced metal. Most periodates are sparingly soluble or insoluble in water, but they all dissolve easily in dilute nitric acid. The solution of the monosodic salt, added to a solution of a barium-, calcium-, lead-, or silver-salt, precipitates the polymetallic or basic periodates of these bases, the liquid acquiring an acid reaction.

Periodate of Ammonium, $(NH^4)IO^4.2H^2O$, separates on mixing the solutions of ammonia and periodic acid. It dissolves in a large quantity of water, and the solution, evaporated at a gentle heat, yields crystals, apparently having the form of rhombic prisms. It has an acid reaction, and explodes when heated in a tube. (Langlois.)

Periodates of Barium.—The monobarytic salt is not known. A *pentabarytic* or

Digitized by Google

pentabasic salt, $Ba^5I^2O^{12}$ or $5BaO.I^2O^7$, is obtained by igniting iodate of barium or a mixture of iodide and peroxide of barium, and dissolving out the iodide of barium from the residue with water. Its solution in nitric acid yields with nitrate of silver a yellow-brown precipitate of basic periodate of silver. (Rammelsberg, Pogg. Ann. xliv. 272.)

A salt containing half as much base as the last, viz. $Ba^5(IO^6)^2.I^2O^7$ or $5BaO.2I^2O^7$, is precipitated by ammonia from the solution of the pentabasic salt, or from a mixture of a soluble barium-salt with monobasic periodate of sodium dissolved in nitric acid; also on mixing nitrate of barium with dibasic periodate of sodium. The precipitate contains 5 at. water, which are given off at 100°; by longer exposure to this temperature, the salt is completely converted into iodate of barium. (Rammelsberg.)

A *dibarytic* or *dibasic* salt, BaH^2IO^6 or $2BaO.3H^2O.I^2O^7$, is obtained by adding baryta-water to a solution of the corresponding sodium-salt mixed with a few drops of nitric acid. It is a white precipitate which decomposes at a red heat, yielding the pentabarytic salt (Langlois):

$$10BaH^2IO^6 = 2Ba^5(IO^6)^2 + I^6 + O^{21} + 15H^2O.$$

Periodates of Calcium.—A *dicalcic salt*, CaH^2IO^6 or $2CaO.3H^2O.I^2O^7$ (at 100°), is obtained by decomposing the sodium salt, NaH^2IO^6, with nitrate of calcium, as a white precipitate, which appears crystalline under the microscope, and when heated gives off water, oxygen, and iodine, and leaves the pentacalcic salt, $Ca^5I^2O^{12}$ (Langlois). The latter is likewise obtained, but mixed with lime, by igniting iodate of calcium in a close vessel.

Periodate of Copper, Cu^2HIO^6 or $4CuO.H^2O.I^2O^7$, is precipitated by mixing the solutions of sulphate of copper and the monosodic salt—a considerable quantity, however, remaining in solution—or by the action of aqueous periodic acid in slight excess of hydrated carbonate of copper. (Langlois.)

Periodates of Iron.—Iron-salts (ferrous or ferric) form, with solution of periodate of sodium, yellowish white precipitates, easily soluble in nitric acid (Benckiser). According to Langlois, periodic acid, in contact with ferrous oxide, is reduced to iodic acid, and ferric iodate separates out. Similar reaction with manganous oxide.

Periodates of Lead.—A *triplumbic* or *tribasic salt*, $Pb^3H^4(IO^6)^2$ or $3PbO.2H^2O.I^2O^7$, is precipitated on mixing 1 at. of the disodic salt with 3 at. nitrate of lead, in microscopic crystals, which do not suffer any loss of weight between 120° and 130°, but, at a higher temperature, give off water, oxygen, and iodine, and leave an oxyiodide of lead containing $PbI^2.5PbO$ (Langlois):

$$2Pb^3H^4(IO^6)^2 = PbI^2.5PbO + O^{15} + I^2 + 4H^2O.$$

Periodate of Lithium, Li^2IO^6?—By treating carbonate of lithium with periodic acid and evaporating the solution at a gentle heat, a crystalline mass is obtained, which dissolves completely in water, and when dried in a vacuum, and then heated to redness, gives off successively water, oxygen, and iodine, but without undergoing complete decomposition. (Langlois.)

Periodate of Magnesium.—Magnesium-salts are not precipitated by solution of periodate of sodium. Carbonate of magnesium, immersed in aqueous periodic acid, is converted into insoluble periodate of magnesium, which dissolves, however, in excess of the acid. The salt consists of small prismatic crystals, which, when dried at mean temperatures, contain $2MgH^2IO^6.9H^2O$ or $2MgO.3H^2O.I^2O^7 + 9$ aq., give off 9 at. water, at 100°, and leave pure magnesia when ignited. (Langlois.)

Periodates of Potassium.—The *monopotassic salt*, KIO^4, is precipitated in sparingly soluble crystalline grains on passing chlorine into a solution of the iodate mixed with potash or carbonate of potassium. Its aqueous solution, mixed with caustic potash, yields the *tetrapotassic salt*, $K^2O.2KIO^4$ or $2K^2O.I^2O^7$, which is also sparingly soluble in water, and is converted by ignition into a mixture of potash and iodide of potassium. The neutral salt when ignited leaves the pure iodide. (Magnus and Ammermüller.)

Periodates of Silver.—Nitrate of silver added to a solution of disodic periodate, throws down a greenish yellow precipitate, which is a basic periodate of silver. By washing it with water containing nitric acid, then dissolving it nearly to saturation in warm nitric acid, and evaporating by heat, the *monoargentic salt*, $AgIO^4$, is obtained in anhydrous orange-yellow crystals. This salt is decomposed by warm water, which dissolves out half the acid, leaving a blackish-brown residue of the *tetrargentic salt*, $2Ag^2O.I^2O^7.H^2O$ or $Ag^8O.2AgIO^4.H^2O$, which turns red by trituration. Cold water decomposes the salt in like manner, but the residual salt is a yellow powder, consisting of $Ag^2H^3IO^6$ or $2Ag^2O.3H^2O.I^2O^7$, and separates from a solution in dilute slightly warmed nitric acid, in straw-yellow crystals, which, according to Rammelsberg

Digitized by Google

(Jahresb. 1857, p. 125), are rhombohedral, exhibiting the combination R . −½R . oR. For R, the ratio of the secondary axes to the principal axis = 1 : 2·0653. Angle R : R in the terminal edges = 74° 0′; oR : R = 112° 45′. The crystals become darker-coloured by exposure to light. On pouring boiling water on these crystals or on the yellow powder, 2 atoms of water are removed, and the red salt above mentioned is produced. (Magnus and Ammermüller.)

Periodates of Sodium.—The *monosodic* salt, $NaIO^4$, is obtained by saturating the disodic salt with periodic acid, and evaporating. It is colourless, very soluble in water, anhydrous, crystallises readily, and is permanent in the air (Magnus and Ammermüller). The crystals are dimetric, P . P∞. For P, the ratio of the secondary axes to the principal axis is 1 : 1·59. Angle P : P in the terminal edges = 99° 30′; in the lateral edges = 132° 4′. The crystals are colourless. (Rammelsberg, *loc. cit.*)

The *disodic* or *dibasic* salt, $Na^2H^3IO^6$ or $2Na^2O.3H^2O.I^2O^7$, is obtained by passing chlorine gas into a hot solution of 1 pt. iodine and 7 pts. carbonate of sodium in 100 pts. water, or into a solution of 1 pt. iodate of sodium mixed with 3 pts. of caustic soda (Magnus and Ammermüller). Langlois uses equal weights of caustic soda and the iodate, and to obtain a solution as concentrated as possible, first dissolves the caustic soda in water, then adds the iodate, and surrounds the filtered solution with hot water while the chlorine is passing into it; the sodic periodate then separates in considerable quantity, as a crystalline powder, having the composition just mentioned. It is sparingly soluble in cold water, somewhat more in warm water, and may be obtained in the crystalline form from a boiling solution of the neutral salt mixed with caustic soda. At a white heat, it gives off 3 at. water and 8 at. oxygen, and leaves an oxyiodide of sodium:

$$2Na^2H^3IO^6 - 3H^2O - O^8 = Na^4I^2O.$$

At a low red heat, it loses only 3 at. oxygen, leaving a residue of *hypo-iodite of* sodium, $Na^4I^2O^3 = 2Na^2O.I^2O$ (or perhaps a compound of iodide and *iodite* of sodium, 2NaI + $3Na^2O.I^2O^3$ or $NaI.Na^2O.NaIO^2$). This compound is sparingly soluble in water, has an alkaline reaction, and bleaches vegetable colours, but loses this property when boiled with water, iodate of sodium being then formed, and the salt becoming easily soluble. On exposure to the air it turns moist, and gradually yields free iodine.

Periodate of Zinc.—Hydrated carbonate of zinc is converted by aqueous periodic acid into a granular powder of periodate of zinc, Zn^2HIO^6 or $4ZnO.H^2O.I^2O^7$, which dissolves readily in excess of the acid, forming a solution, which, when evaporated at a gentle heat, yields laminar crystals of another salt containing $3ZnO.7H^2O.2I^2O^7$, *i.e.* a double per-iodic molecule, $Zn^3H^{14}I^4O^{24} = \left.\begin{matrix}(\overline{IO})^4\\ Zn^3H^{14}\end{matrix}\right\}O^{20}$. (Langlois.)

IODINE, SELENIDE, SULPHIDE, and **TELLURIDE OF.** See Selenium, Sulphur, and Tellurium, Iodides of.

IODITE, IODOPYRITE, IODIC SILVER. Native iodide of silver. (See Silver, Iodide of.)

IODOBENZOIC ACID. $C^7H^5IO^2$.—An acid produced by the action of hydriodic acid on diazobenzo-oxybenzamic acid:

$$\underset{\text{Diazobenzo-oxybenzamic acid.}}{C^{14}H^{11}N^3O^4} + 2HI = \underset{\text{Hydriodate of oxybenzamic acid.}}{C^7H^7NO^2.HI} + \underset{\text{Iodobenzoic acid.}}{C^7H^5IO^2} + N^2.$$

It crystallises in needles, is heavier than water, easily soluble in alcohol; sublimes without decomposition; forms a white silver-salt, $C^7H^4AgIO^2$, insoluble in water and in alcohol; is converted by fuming nitric acid into nitro-iodobenzoic acid. (Griess, Ann. Ch. Pharm. cxiii. 201.)

IODOBRUCINE. Syn. with Iodide of Brucine. (See Brucine, i. 683.)

IODO-CAOUTCHIN. See Caoutchin (i. 737).

IODO-CHLORO-NITROHARMINE. Syn. with Di-iodide of Chloro-nitro-harmine. (See Harmine, iii. 12).

IODOCINCHONINE. See Cinchonine (i. 979).

IODOCINNAMIC ACID. $C^9H^7IO^2$?—When cinnamic acid is melted with excess of iodine, and the dark brown mass is boiled with water till all the free iodine is volatilised, the liquid on cooling yields small colourless stellate crystals of iodocinnamic acid, which acquire a faint yellow colour on exposure to the air. The acid dissolves easily in hot water and in alcohol. (Herzog, N. Br. Arch. xx. 147.)

IODOCODEÏNE. Syn. with Iodide of Codeïne. (See CODEÏNE, i. 1068).

IODOFORM. CHI^3. *Di-iodated iodide of methyl.* (Gm. vii. 330; Gerh. i. 609.) —This compound, which was discovered in 1824 by Serullas (Ann. Ch. Phys. xxv. 314), is produced by the action of iodine and alkalis or alkaline carbonates on wood-spirit, alcohol, or ether; in small quantity also by the action of the same substances on cane-sugar, glucose, gum, dextrin, and several albuminous substances. It has also been observed among the products obtained by heating glycerin with hydriodic acid. (Erlenmeyer, Jahresb. 1861, p. 668.)

Preparation.—1 pt. of alcohol is added to a solution of 2 pts. crystallised carbonate of sodium in 10 pts. water; the liquid is heated to 60 or 80°; and 1 pt. of iodine is added by small portions, till it is entirely dissolved, and the liquid has become colourless. Iodoform then makes its appearance towards the end of the operation and sinks to the bottom of the hot liquid, which must be filtered to collect this first portion of the product. The mother-liquor is then again heated to 60° or 80°; another portion of carbonate of sodium, equal to the former, is dissolved in it; a fresh portion of alcohol is added; and a current of chlorine is passed into the liquid, which must be continually agitated, so that the iodine which separates may mix well with it. When the process is so conducted that a slight excess of iodine is constantly present, iodoform is produced in abundance. When a considerable quantity has been deposited, the stream of chlorine is interrupted, the liquid is left to decolorise, and the second portion of iodoform is added to the first. The mother-liquor may then be treated with chlorine and a third portion of iodoform obtained. The process, when properly conducted, yields a quantity of iodoform weighing 40 or 50 per cent. of the iodine used. Care must be taken, throughout the operation, to avoid a great excess of iodine, as in that case the iodoform will not be produced at all. Borax may be used instead of carbonate of sodium, and will yield a product of equal amount. With phosphate of sodium the product is not so good. (Filhol, J. Pharm. [3] vii. 267.)

Cornelius and Gille (*ibid.* xxii. 196) prepare iodoform by adding hypochlorite of calcium to an alcoholic solution of iodide of potassium heated to 40°, continuing the addition till the liquid becomes colourless. It then on cooling yields a crystalline deposit, consisting of iodoform mixed with iodate of calcium, from which the iodoform may be dissolved by boiling alcohol. 8 pts. of iodide of potassium yield, by this process, 2 pts. of iodoform and 2 pts. of iodate of calcium.

Properties.—Iodoform crystallises in nacreous scales, friable, soft to the touch, having a sulphur-yellow colour and the odour of saffron. According to Rammelsberg and Kokscharow (Jahresber. 1857, p. 431), the crystals are hexagonal combinations oP . P. For P the ratio of the secondary axes to the principal axis is 0·9025 : 1. Angle P : P in the terminal edges = 133° 36′; in the lateral edges = 104°. Specific gravity about 2·0. Melts between 115° and 120°, and then vaporises, partly without alteration, partly resolved into iodine and hydriodic acid, with a residue of charcoal. With vapour of water it distils undecomposed. It is not perceptibly soluble in *water*, *acids*, or aqueous *alkalis*, but dissolves readily in *alcohol*, *ether*, and *oils*, both fixed and volatile.

Decompositions.—1. Iodoform heated in a sealed tube to 150°, either alone or with *iodine*, is resolved into di-iodide of methylene, and a number of brown substances not yet examined (Hofmann, Chem. Soc. J. xiii. 65).—2. Iodoform is acted upon by *bromine*, yielding bromiodoform, $CHBrI^2$.—3. With moist *chlorine*, it yields chlorocarbonic oxide, hydrochloric acid, and protochloride of iodine:

$$CHI^3 + H^2O + Cl^2 = COCl^2 + 3HCl + 3ICl.$$

—4. Heated with *pentachloride of phosphorus*, it yields an oily liquid, perhaps chloroform, or according to Butlerow, di-iodide of methylene, CH^2I^2.—5. Distilled with *chloride of mercury*, *lead*, or *tin*, it yields chloriodoform, $CHCl^2I$.—6. Distilled with *sulphide of mercury*, it yields a small quantity of an oily liquid, which, according to Bouchardat (J. Pharm. xxiii. 12) is sulphoform, C^2HS^3; but according to Eggert (Chem. Centr. 1857, p. 513) is nothing but disulphide of carbon.—7. With *cyanide of mercury* or *cyanide of silver* it yields a sublimate of iodide of cyanogen.—8. When *cyanogen gas* is passed into an alcoholic solution of iodoform, the liquid becomes heated and assumes a violet tint; and if then left at rest, deposits golden-yellow, prismatic crystals, from which alcohol extracts two substances having a strong metallic lustre; one with a greenish gold, the other with a violet colour; the latter appears to be *cyanide of di-iodomethyl*, $CHI^2.Cy$ (St.-Evre, Compt. rend. xxvii. 533).—9. Heated with alcoholic solution of *sulphocyanate of potassium* to 100° in sealed tubes, it yields a gas and oily compound which has an odour of horse-radish, and forms a crystalline compound with ammonia, though not so readily as oil of mustard (Hlasiwetz, Ann. Ch. Pharm. cxii. 184).—10. *Mercuric oxide* gently heated with iodoform acts energetically upon it, producing

Digitized by Google

water, carbonic anhydride, formic acid, and mercuric iodide.—11. Iodo with *aqueous potash* is partly converted into formate and iodide of potassiu however, volatilising with the watery vapour.—12. With *alcoholic potas* liquid which Brüning, who first obtained it (Ann. Ch. Pharm. civ. 187) C^2HI^3O, but which, according to Butlerow, is di-iodide of methylene. *ethylate of sodium*, iodoform yields iodide of methylene, CH^2I^2, together w sodium and aldehyde (Butlerow, Ann. Ch. Pharm. cvii. 110):

$$C^2H^5NaO + CHI^3 = CH^2I^2 + NaI + C^2H^4O.$$

According to more recent experiments by Butlerow (*ibid.* cxiv. 204; c appears that acrylic acid, $C^3H^4O^2$, and ethyl-lactic acid, $C^5H^{10}O^3$, are like in this reaction.

14. Iodoform heated with *potassium* produces a violent explosion.

15. With *triethyl-phosphine*, iodoform unites directly, without the aid of h the tri-iodide of formyl-nonethyl-triphosphonium (Hofmann, Proc. Roy. S

$$CHI^3 + 3(C^2H^5)^3P = C^{19}H^{46}P^3I^3 = [(CH)'''(C^2H^5)^9P^3]'''$$

IODOLITE. A meteoric mineral mentioned by C. U. Shepard amo of others which have been but imperfectly described. (Sill. Am. J. [2] 402; xv. 363.)

IODOMECONE. $C^9H^4I^2O^3$. (J. Brown, Edinb. Phil. Trans. xxi. substance formed by treating pyromeconic acid with excess of prot iodine:

$$C^5H^4O^3 + 8ICl + 4H^2O = C^9H^4I^2O^3 + 2CO^2 + 8HCl$$

On adding potash to the yellow liquid thus obtained (after separation of a tity of iodopyromeconic acid) impure iodomecone is obtained as a blac which redissolves on agitation. The addition of potash must be discontin as this precipitate exhibits a lighter colour, no longer redissolves on agit not increased by fresh additions; and by then collecting the precipitate, it with cold water, and repeatedly crystallising it from boiling alcohol, ic obtained in the pure state. It may be obtained in the same manner fro comenic acid, which differ from pyromeconic acid only by the elements anhydride.

Iodomecone forms shining yellow hexagonal plates, having an odour v that of saffron; it has neither an acid nor an alkaline reaction, sublimes is insoluble in water, soluble in alcohol and in ether, insoluble in hydr which does not decompose it even at the boiling heat. It is decompose nitric acid, and with aid of heat by strong sulphuric acid. Caustic potas boiling, abstracts from it a small portion of iodine.

IODO-SUBSTITUTION COMPOUNDS. Iodine, though generally speaking very similar in its action to chlorine and bromine, acts for the most part less energetically, and is much less disposed to form substitution-compounds by direct action. Some compounds containing hydrogen, indeed, are acted upon by iodine in the same manner as by bromine or chlorine, part of the hydrogen being abstracted to form hydriodic acid, and its place being supplied by an equivalent quantity of iodine; such is the case with ammonia (iii. 280), ethylamine (ii. 536), methylamine, and phenylamine. But iodated organic acids cannot, for the most part, be formed in this way; to produce them from the original acids it is necessary to use chloride of iodine instead of free iodine, so that the superior affinity of the chlorine for hydrogen may remove it, and enable the iodine to take its place (p. 294) *e. g.*:

$$\underset{\text{Pyromeconic acid.}}{C^5H^4O^3} + ICl = HCl + \underset{\text{Iodopyromeconic acid.}}{C^5H^3IO^3}.$$

On the other hand, Kekulé (Chem. Soc. J. xvii. 206) has lately shown that many iodo-substitution compounds are decomposed by hydriodic acid, iodine being set free and the original acid reproduced, *e. g.*:

$$\underset{\text{Iodopropionic acid.}}{C^3H^3IO^2} + HI = \underset{\text{Propionic acid.}}{C^3H^4O^2} + I^2.$$

It is evident that where this reaction takes place, it is impossible that an iodised compound can be produced by the direct action of iodine on an organic acid. [For an exception, perhaps only apparent, to this rule, see SALICYLIC ACID.]

The action of hydriodic acid on iodated organic compounds just noticed explains the reducing action which it exerts on certain organic acids (p. 285). The reaction takes place in two stages, an iodo-substitution compound being first formed, and subsequently decomposed in the manner above explained. *e. g.*:

$$\underset{\text{Glycollic acid.}}{C^2H^4O^2} + HI = H^2O + \underset{\text{Iodacetic acid.}}{C^2H^3IO^2}.$$

$$\underset{\text{Iodacetic acid.}}{C^2H^3IO^2} + HI = I^2 + \underset{\text{Acetic acid.}}{C^2H^4O^2}.$$

IOLITE. Syn. with DICHROÏTE (ii. 320).

IONNAPHTHIN. This name is given by Carey Lea (Sill. Am. J. [2] xxxii. 211) to a colouring matter obtained in preparing naphthylamine from nitronaphthylene by the action of ferrous acetate (*Gmelin's Handbook*, xiv. 95, 5). If the mixture is heated before being treated with caustic potash, a faint red-coloured liquid distils over, which turns violet on addition of mineral acids, and if subsequently heated, assumes a dark purple-blue colour, and after a while yields a black crystalline precipitate, the quantity of which is increased by further heating; this is ionnaphthin. The crystals are black, with green metallic reflex, and dissolve in alcohol with blood-red colour, which, on addition of a very small quantity of sulphuric or nitric acid, changes to scarlet, and finally to purple-blue, is not altered by heating with sulphuric acid, but is changed to straw-yellow by hot nitric acid. From the brown mother-liquor, ammonia throws down dark-coloured flocks, which are insoluble in water and in alcohol, are blackened by dilute sulphuric acid and bichromate of potash, and then form a violet solution with dilute nitric acid.

IPECACUANHA. An emetic substance, the root of several plants growing in South America. All the kinds have nearly the same ingredients, but differ in the amount of the active principle (*emetin*) which they contain. The best is the annulated, yielded by *Cephalis Ipecacuanha*, a small shrubby plant of the rubiaceous order, native of Brazil and New Granada. It is found in commerce in pieces from 2 to 6 inches long and about the thickness of a straw, much bent or twisted, and sometimes branched, with a remarkably knotty character, owing to numerous circular depressions or clefts, which give the whole the appearance of a number of rings. It consists of a central axis called *meditullium*, and an external portion called the *cortical part*. Each of these contains emetin, but by far the greater portion exists in the cortical part.

a. Grey ipecacuanha, analysed by Barruch and Richard (the 2·4 per cent. gum includes saline matters). *b*. Blackish-grey, analysed by Pelletier. *c*. Reddish-grey, deprived of its meditullium, analysed by Pelletier. In an ash-grey variety, Pelletier found 9 per cent. fatty matter, 12 emetin, and 79 starch, gum, and woody fibre.

Another sort of ipecacuanha is obtained from the *Psychotria emetica*. This kind contains only 9 per cent. emetin; and the undulated or amylaceous ipecacuanha, the produce of *Richardsonia scabra*, contains only 6 per cent. emetin, with 92 per cent. starch. Besides these, the roots of numerous other plants are used in tropical countries as emetics, and often termed ipecacuanha. (Pelouze et Frémy, *Traité*, vi. 399.—*Penny Cyclopædia*, xiii. 17.—Rochleder, *Phytochemie*, s. 131.)

IPECUANIC ACID. An acid existing, according to Willigk (Ann. Ch. Pharm. lxxvi. 342), in the root of *Cephalis Ipecacuanha*. It is extracted from the root by boiling with alcohol, precipitating with basic acetate of lead, and decomposing the lead-salt with sulphydric acid. It is a reddish-brown, very bitter, amorphous mass, soluble in ether, more soluble in alcohol and water. It colours ferric salts green, the colour being changed to violet by ammonia. Its dilute solution does not precipitate neutral acetate of lead. When mixed with an alkali, it absorbs oxygen from the air and becomes coloured. It gives by analysis 56·22 per cent. C, and 6·23 H, whence Willigk deduces the formula $C^{14}H^{18}O^{7}$. Pelletier (Ann. Ch. Phys. iv. 172) regarded it as gallic acid.

IPOMEIC ACID. An acid produced by the action of nitric acid on rhodeoretic acid, a derivative of jalap-resin (*q. v.*) It agrees with sebacic acid in all its properties excepting its melting point—which is 104°, whereas sebacic acid melts at 127°—and in some of its relations to bases (Mayer, Ann. Ch. Pharm. lxxxiii. 143). See SEBACIC ACID.

IRIDIUM. Ir. *Atomic weight* 198·26.—The black scales which remain when native platinum is dissolved in nitromuriatic acid were found by Smithson Tennant (Phil. Trans. 1804) to consist of an alloy of two metals, iridium and osmium, hence called iridosmine. The same alloy occurs in flat white metallic grains in native platinum. Iridium has also been observed in combination with about 20 per cent. of platinum, crystallised in octahedrons, which are whiter than platinum, and are said to have a greater density, namely 22·66.

The separation of the osmium and iridium is effected by the following methods:—

1. The iridosmine is mixed with an equal weight of common salt, and subjected to the action of a stream of chlorine in a porcelain tube heated to redness. Double chlorides of iridium and sodium, and of osmium and sodium, are then formed, and if the chlorine is moist, a certain quantity of osmic acid, which volatilises, and may be condensed in aqueous ammonia. The mixture of the double chlorides is detached from the tube and boiled with nitric acid. Osmic acid is then evolved, and may be condensed in an alkaline solution, while the chloride of sodium and iridium remains in the solution, and, when mixed with sal-ammoniac, yields a precipitate of chloride of iridium and ammonium, which, on ignition, leaves metallic iridium. (Wöhler, Pogg. Ann. xxxi. 161.)

2. A mixture of 100 grms. of iridosmine and 300 grms. of nitre is placed in an earthen crucible, and heated to bright redness for an hour, the resulting mixture of osmate and iridiate of potassium poured out on a cold metal plate, then introduced into a tubulated retort, and distilled with a large excess of nitric acid. runs away coloured, then with a more dilute solution of the same salt; the residue, chiefly consisting of chloriridiate of ammonium, is dried, heated to commencing redness (so as to decompose the ammonium-salts completely, the chlorides of the platinum metals imperfectly), then in a current of hydrogen to complete the reduction; and the resulting metallic sponge, in which the metals are not alloyed, but only mechanically mixed, is treated with nitromuriatic acid, which completely removes any platinum that may still be present, but leaves behind a certain quantity of osmium. The remaining pulverulent metallic mass is then fused with a mixture of nitrate and hydrate of potassium; and the unattacked portion of the metal, after being carefully freed from rutheniate of potassium by washing with water, is heated to whiteness in a crucible lined with charcoal, in which it bakes together; then placed in a vessel of lime and ignited in an oxy-hydrogen flame containing excess of oxygen, till every trace of the odour of osmium has disappeared; and lastly, fused at the strongest heat which the oxy-hydrogen flame is capable of producing. (Deville and Debray, Ann. Ch. Phys. [3] lvi. 385; Rép. Chim. pure, 1859, p. 541; Jahresber. 1859, p. 241.)

6. An intimate mixture of 100 pts. iridosmine or platinum-residues, 100 pts. nitrate of barium and 200 pts. caustic baryta, is heated in a red-hot earthen crucible; and the fritted mass, after being pulverised, is thrown by small portions into cold water, then mixed with nitric acid, and heated till all the osmium is driven off as osmic acid. A small quantity of hydrochloric acid is then added; the liquid is heated and filtered through gun-cotton; and the iridium is separated from the other metals contained in it, as in the preceding method. (Deville and Debray, Compt. rend. liv. 1138.)

7. Platinum-residue, finely pulverised and freed by levigation from the coarser grains of osmide of iridium, is gently ignited in a covered crucible, then mixed with 1 pt. finely granulated lead and 1½ pt. litharge, and heated, with stirring, in a thick-bottomed hessian crucible till the mixture becomes perfectly fluid. By this means all the silicates and earthy minerals present are converted into a slag; the metals more oxidable than lead are oxidised; and the specifically heavier platinum-metals collect in the lead-regulus. The latter, after being freed from slag, is dissolved at a gentle heat in nitric acid diluted with 1½ vol. water, which dissolves principally copper and palladium, leaving a residue which, when washed by decantation, consists of a fine black metallic powder of iridium, rhodium, and ruthenium, together with fine grains and scales of iridosmine, which must be separated by levigation. The black powder is immediately available for further treatment; the iridosmine, on the other hand (together with the coarser grains obtained by levigating the crude platinum-residue), is reduced to powder by fusing it in a charcoal crucible with twice its weight of granulated zinc, and then raising the heat to whiteness to drive off the zinc (p. 315). The finely divided iridosmine, is then heated in a stream of oxygen to expel the osmium, and the residue, together with the black powder of iridium, rhodium, and ruthenium above-mentioned, is mixed with an equal weight of chloride of sodium, and decomposed by Wöhler's method with chlorine gas (p. 314). The dark brown solution thus obtained is mixed with a little hydrochloric acid and one-fourth of its bulk of ordinary nitric acid, and distilled to one-third, the osmic acid which passes over being condensed by ammonia; the remaining liquid, which contains the double chlorides of iridium, &c., is mixed, while still warm, with an equal volume of a saturated solution of sal-ammoniac; and the red-brown precipitate, after standing for some days, is separated from the liquid, and washed with sal-ammoniac solution till the liquid runs off colourless. The wash-water contains the whole of the rhodium-salt, the mother-liquor consists chiefly of chloride of iron and ammonium, with traces of iridium, rhodium, and gold. The precipitate, consisting of chloriridiate of ammonium contaminated with platinum and ruthenium-salt, is mixed, after drying, with 1½ pt. cyanide of potassium, and melted for 10 or 15 minutes in a capacious porcelain crucible; the cooled mass is dissolved in the smallest possible quantity of water; and the yellow filtrate (after the whole of the free cyanide of potassium has been decomposed by dilute hydrochloric acid) is precipitated by sulphate of copper. The resulting precipitate, consisting chiefly of platino- and iridio-cyanide of copper, is washed with boiling water, first by decantation, then on a filter, and finally decomposed with boiling baryta-water, whereby oxide of copper is separated, and the platinum and iridium are converted into platino- and iridio-cyanides of barium, which are easy to separate, the platinum-salt, which is much more soluble in hot than in cold water, separating out completely at first, and the white iridium-salt crystallising afterwards. The mother-liquor of the iridium-salt contains a small quantity of ruthenio-cyanide of potassium; any rhodium-salt that may be present may be precipitated by acetic acid. (C. A. Martius, Ann. Ch. Pharm. cxvii. 357; Jahresber. 1860, p. 202.)

8. The following process is given by Deville and Debray (Ann. Ch. Phys. [3] lxi. 5; Jahresb. 1861, p. 889) for obtaining iridium, pure or alloyed, from the substance

Digitized by Google

known in the Russian mint as "iridium-oxide"—a not quite uniform mixture containing iridium as oxide, and having the following average composition:

Volatile substances (and oxygen)	28·0
Soluble salts (NaCl and $CaSO^4$)	12·0
Platinum	3·8
Rhodium	1·8
Palladium	0·4
Copper	0·6
Iron	0·7
Iridium (and loss)	52·7
	100·0

The substance is ignited in a crucible lined with charcoal; and the residue is washed with water, heated with strong sulphuric acid to the boiling point of that liquid, and again washed with water, whereby all the soluble salts are removed, together with the copper and iron. If the amount of platinum is known, and the object is to prepare an alloy, the washed metal is heated to whiteness (to give it a compact texture), and then fused before the oxy-hydrogen blowpipe. To obtain pure iridium, the crude metallic powder, after treatment with sulphuric acid, is digested with nitromuriatic acid, the greater part of the iridium (with traces of rhodium) then remaining behind.

Metallic iridium is obtained from the chloride by reducing that salt with hydrogen at a red heat, or by exposing it alone to a very high temperature, or more easily by igniting the chloriridiate of ammonium (p. 314), in the form of a grey metallic powder much resembling spongy platinum. It is the most refractory of all bodies excepting ruthenium and osmium; not being fusible in the flame of the ordinary oxy-hydrogen blowpipe. Children, however, by the discharge of a very large voltaic battery, succeeded in melting it into a globule which was white and very brilliant, but still a little porous, and had a density of 18·68; and Deville and Debray, by means of their powerful oxy-hydrogen blast furnace, have fused it completely into a pure white mass, resembling polished steel, brittle in the cold, somewhat malleable at a red heat, and having a density equal to that of platinum, viz. 21·15. By moistening the pulverulent metal with a small quantity of water, pressing it tightly, first between filtering paper, then very forcibly in a press, and calcining it at a white heat in a forge-fire, it may be obtained in the form of a compact, very hard mass, capable of taking a good polish, but still very porous, and of a density not exceeding 16·0. After strong ignition it is insoluble in all acids, but when reduced by hydrogen at low temperatures, it oxidises slowly at a red heat, and dissolves in nitromuriatic acid. It is usually rendered soluble by fusing it with nitre and caustic potash, or by mixing it with common salt, or better with a mixture of the chlorides of potassium and sodium, and igniting it in a current of chlorine, thereby it is converted into the soluble chloriridiate of potassium or sodium.

IRIDIUM, ALLOYS OF. 1 pt. of iridium combines at a white heat with 4 pts. of copper, forming a ductile, pale red alloy, which is much harder than copper, and gives up its copper to nitric acid, the iridium remaining in the form of a black powder.

With gold, iridium forms a malleable alloy, having a colour very much like that of gold: nitromuriatic acid dissolves out the gold and leaves the iridium.

1 pt. of iridium and 8 pts. lead heated together to an intense red heat, form an alloy which is very ductile, but much harder and whiter than lead, and behaves with nitric acid like the copper alloy. On cupellation, the iridium is left as a soft black powder.

With mercury, iridium forms a viscid amalgam, which is obtained by immersing sodium-amalgam in an aqueous solution of chloriridiate of sodium. When very strongly ignited, it leaves a black powder, from which boiling nitric acid extracts a small quantity of mercury, leaving a residue of pure iridium, soluble in boiling nitromuriatic acid. (Böttger, J. pr. Chem. xii. 252.)

The compound of iridium and osmium is not, properly speaking, an alloy, inasmuch as osmium is rather a metalloïd than a metal. (See IRIDOSMINE.)

Platinum and iridium easily melt together, and form alloys which, even when they contain 20 per cent. of iridium, are still malleable and capable of being worked, but are less easily attacked by chemical reagents than pure platinum. (Deville and Debray.)

Equal weights of the two metals form a brittle alloy capable of welding to a certain extent. The alloy of platinum with a few parts per cent. of iridium is ductile and much harder than pure platinum, and more capable of resisting the action of fire and of chemical reagents (Berzelius). An alloy made by fusing 1 pt. iridium and 10 platinum in the

Digitized by Google

flame of the oxyhydrogen blowpipe, is very malleable, susceptible of harden not tarnish, and when laid on copper serves for metallic mirrors. (Gaudi Chem. xvi. 55.)

A native alloy of iridium and platinum called native iridium occurs in in cubo-octahedrons of specific gravity varying from 21·85 to 22·65 and 22· Brazil in white round grains of specific gravity 16·94. (Svanberg, *Gmelin'* vi. 393.)

1 pt. of iridium unites but imperfectly with 2 pts. of silver. (Vauqueli

1 pt. of iridium unites with 4 pts. of tin at an intense red heat, forming a d easily crystallisable, hard, malleable alloy. (Vauquelin.)

When iridosmine is fused with from 5 to 6 times its weight of tin, the all kept for a long time at a red heat in the charcoal crucible, then slowly co treated with hydrochloric acid, tin passes into solution, together with traces of and there remains a mixture (separable by a fine sieve) of finely pulverulent c osmium, and large shining cubic crystals of an alloy of tin and iridium, whi attacked by nitromuriatic acid, but when strongly ignited in an atmosphere of dric acid, gives off the whole of the tin, amounting to 56·6 per cent., as leaving 43·4 per cent. iridium.—By fusing tin with a mass containing iridium, and rhodium, and dissolving the excess of tin in hydrochloric crystalline residue is obtained, whose composition (if Pt denotes the platinu in general) is $PtSn^4$. (Deville and Debray.)

An alloy of iridium and zinc, obtained as in Deville and Debray's first m preparing an alloy of iridium and tin, is not crystallisable.

IRIDIUM, CARBIDE OF. When a coherent mass of iridium is he flame of a spirit-lamp, black masses appear on its surface, which are s containing 19·83 per cent. carbon, or IrC^4. The carbon burns off readily in

IRIDIUM, CHLORIDES OF. Iridium appears to form four compou chlorine; but only two of them have been obtained in definite form.

The *dichloride*, $IrCl^2$, is said by Berzelius to be formed when p iridium is heated to low redness in chlorine gas. It is described as a dark o powder, insoluble in water, slightly soluble in hydrochloric acid, and formi salts with the chlorides of the alkali-metals. According to Claus, however (Pharm. lix. 255), the so-called dichloride of iridium is merely a mixtur trichloride with metallic iridium. The dichloride appears, however, to certain double salts (p. 322).

The *trichloride*, Ir^2Cl^6, is prepared by dissolving the sesquioxide in hy acid, and evaporating; it also sublimes when iridium, either alone or mi nitre, is ignited in chlorine gas. It is black, deliquescent, and does not c It unites with the chlorides of the alkali-metals, forming double salts, called iridites, which are prepared, either by mixing the solutions of the c chlorides in the required proportions, and evaporating, or by reducing the of the corresponding chloriridiates with sulphurous acid, sulphydric acid or ferrocyanide of potassium. Claus has obtained the compounds $6NH^4$ $6H^2O$, $6KCl.Ir^2Cl^6.6H^2O$, and $6NaCl.Ir^2Cl^6.24H^2O$. They are olive-green, lent salts, soluble in water; the sodium-salt is also soluble in alcohol; two are insoluble in alcohol. Berzelius obtained a potassium-salt c $4KCl.Ir^2Cl^6$.

Chloriridite of silver, $Ag^6Ir^2Cl^{12} = 6AgCl.Ir^2Cl^6$, is produced, on adding silver to aqueous chloriridiate of potassium, as a deep indigo-coloured precipitate, which, however, becomes paler in a few seconds, and finally loses altogether. The reaction, which is attended with evolution of oxygen, is:

$$6AgNO^3 + 2K^3IrCl^6 + H^2O = Ag^6Ir^2Cl^{12} + 4KNO^3 + 2HNO^3 +$$

With a boiling solution of chloriridiate of potassium, the same compound immediately, without the intermediate production of a blue substance. T salt is insoluble in water and in acids, and but slightly soluble in ammoni it is covered with strong aqueous ammonia and left to itself for a few days, o dissolves, and the remainder is converted into a crystalline modification c composed of rhombohedrons having an adamantine lustre. (Claus, Ann. C lxiii. 338.)

The *tetrachloride*, $IrCl^4$, is obtained by dissolving very finely divide or one of its oxides, or the trichloride, in nitromuriatic acid, and he liquid to the boiling point. On evaporating the solution, it remains in of a black, deliquescent, amorphous mass, translucent with dark red col

Digitized by Google

edges. It sustains a rather strong heat without decomposition, but at a higher temperature is reduced to the trichloride and ultimately to metallic iridium (Berzelius). It dissolves in water, forming a reddish-yellow solution. It unites with the alkaline chlorides, forming definite crystalline double salts called chloriridiates, the general formula of which is $M^2IrCl^6 = 2MCl.IrCl^4$. The *ammonium-salt*, $2NH^4Cl.IrCl^4.H^2O$ or $(NH^4)^2IrCl^6.H^2O$, is obtained, on mixing the solutions of the component chlorides, as a very dark brown precipitate, which dissolves in boiling water and crystallises in octahedrons on cooling. It dissolves in 20 pts. of cold water, forming a dark red brown liquid, and imparts distinct coloration to 4,000 pts. of water. The red colour often exhibited by chloroplatinate of ammonium is due to small quantities of this salt. The aqueous solution supersaturated with ammonia forms a pale yellow mixture, which becomes perfectly colourless when exposed to light, but afterwards turns purple, then violet, and finally assumes a beautiful blue colour.

The chloriridiates are easily converted, by the action of sulphurous acid, sulphydric acid, and other reducing agents, into the more soluble chloriridites, a reaction which affords the means of separating iridium from platinum, the chloroplatinates being but very slowly reduced under the same circumstances, and not converted into more soluble salts (p. 315).

The *potassium-salt*, $K^2IrCl^6 = 2KCl.IrCl^4$, is precipitated on mixing the aqueous solutions of its component salts. It may also be prepared by passing chlorine gas over a gently ignited and intimate mixture of finely divided iridium and chloride of potassium; filtering from unaltered iridium; dissolving the unfused black-brown mass in hot water; mixing it with nitromuriatic acid and evaporating to dryness; extracting the excess of chloride of potassium by small quantities of cold water; dissolving the residue in boiling water; adding a small quantity of nitromuriatic acid; and evaporating to the crystallising point. It crystallises in black octahedrons, yielding a red powder. It dissolves very slowly in cold water, but quickly in boiling water, forming a liquid which appears deep red in the mass, but yellow in thin films. It is insoluble in saline solutions and in alcohol, which precipitates it from solution in water. The aqueous solution, mixed with excess of potash, behaves in the same manner as the ammonium-salt with excess of ammonia. At a strong heat, it is converted into chloriridite of potassium, and at a still higher temperature, leaves metallic iridium mixed with chloride of potassium. The *sodium-salt*, $Na^2IrCl^6.6H^2O$ or $2NaCl.IrCl^4.6H^2O$, is obtained, like the potassium-salt, by passing chlorine over a gently ignited mixture of iridium and chloride of sodium. It forms black tables and four-sided prisms with dihedral summits, isomorphous with the corresponding platinum-salt. When heated, they leave the anhydrous salt in the form of a brownish-grey powder. It is easily soluble in water, and the solution mixed with sal-ammoniac yields a precipitate of chloriridiate of ammonium.

A *hexchloride* of iridium was obtained by Berzelius, in combination with chloride of potassium, by fusing iridosmine with nitre, distilling the product with nitromuriatic acid, and treating the residue with successive portions of water. A dark red solution was then obtained, which yielded a salt having the composition $6KCl.IrCl^4$, but according to Claus, the salt thus obtained was really a ruthenium-compound, having been prepared by Berzelius from iridosmine containing ruthenium. Pure iridium fused with nitre and distilled with nitromuriatic acid, yields a salt containing dichloride of iridium.

IRIDIUM, DETECTION AND ESTIMATION. Iridium in its free state is easily distinguished from all other metals, excepting rhodium and ruthenium, by its insolubility in acids, not being attacked in the compact state by any acid whatever, and in the state of fine division, only very slowly by nitromuriatic acid. Its infusibility, even in the ordinary oxy-hydrogen blowpipe flame, serves also to distinguish it from all metals excepting rhodium, ruthenium, and osmium.

It may be distinguished from rhodium by fusing it in the finely divided state with acid sulphate of potassium. The iridium is then converted into sesquioxide, but does not dissolve in the acid sulphate or colour it red, as rhodium does. Another method of distinguishing iridium from rhodium, and likewise from ruthenium, is to mix it intimately with chloride of potassium or sodium, heat the mixture in a stream of chlorine, and dissolve the resulting double chloride in water: iridium thus treated yields a black-brown solution, rhodium a rose-red, and ruthenium an orange-yellow solution. (See RHODIUM and RUTHENIUM.)

All compounds of iridium are easily reduced to the metallic state by ignition in an atmosphere of hydrogen; the reduced metal may then be tested in the manner just described.

Iridic solutions (containing the dioxide or tetrachloride), which are those of most frequent occurrence, are of a dark brown-red colour; iridous solutions (containing the sesquioxide or trichloride) have an olive-green colour. The characters of an iridic solution are best observed with chloriridiate of sodium, as all the other compounds are but very slightly soluble.

Digitized by Google

Caustic *potash* in excess decolorises the solution of an iridic salt, changing red colour to a very faint greenish tint, and after some time throws down black-brown precipitate of chloriridiate of potassium. If the clear solution b and then left in contact with the air, it first acquires a faint red and the colour, gradually increasing in intensity from the surface downwards, and u becoming as deep as that of an ammoniacal solution of copper. The solutio rated to dryness, leaves a white mass, which, when treated with water, yields less solution and an insoluble blue powder consisting, according to Claus, hydrate. This is the most characteristic of all the reactions of iridium. The of *palladium* interferes, however, with the production of the blue colour, and to the precipitation of iridic oxide. A solution of iridium containing *platinu* wise not coloured blue by potash, but is decolorised, and yields a red preci chloroplatinate of potassium containing iridium; on heating the liquid, this p redissolves, and another precipitate is formed consisting of platiniferous iridi If the solution contains *rhodium*, no alteration takes place at first; but subs a light yellow precipitate of rhodic hydrate is produced; or if the solution is precipitate is of a dirty greyish-green colour, and the solution becomes colourl

Ammonia in excess also decolorises iridic solutions, and forms a slight blac cipitate. On boiling the solution for some time, till the greater part of the is expelled, the solution acquires a blue colour, especially if left exposed to but the colour is neither so pure nor so deep as that produced by potash. sence of palladium, platinum, or rhodium modifies the reaction with ammonia the same manner as with potash. *Carbonate of potassium* forms a red-brow pitate, which gradually dissolves, the liquid afterwards turning blue when ex the air. *Carbonate of ammonium* imparts a blue colour to the liquid unde fluence of the air. *Sulphydric acid* decolorises the solution at first, and af forms a brown precipitate. *Chloride of ammonium* forms a dark cherry-red, lent precipitate of chloriridiate of ammonium. *Ferrocyanide of potassium* a *sulphate of iron* decolorise the solution. *Dichloride of tin* forms a ligh precipitate. *Zinc* precipitates metallic iridium as a black powder.

Quantitative estimation and separation.—Iridium is completely tated from the solution of an iridic salt by treating the solution with chlorid monium or chloride of potassium, and then adding alcohol containing ether, in v chloriridiate of ammonium or potassium is quite insoluble. The precipitate collected on a weighed filter, washed with alcohol and ether, dried in the wa and then weighed. The ammonium-precipitate contains 44·21 per cent., the po precipitate 40·38 per cent. iridium. The ammonium-precipitate may also, after with ether-alcohol (not on a weighed filter), and drying, be carefully ignited i platinum crucible, and the weight of the remaining iridium directly determine

If the iridium exists in solution as sesquichloride, it must, before precipit converted into dichloride by passing chlorine gas into it, or heating it wit muriatic acid.

The mode of precipitation just described serves for the separation of iridi all metals excepting platinum, rhodium, ruthenium, and osmium; and from except rhodium, it may be separated by reducing it to the state of sesquichlo then adding to the liquid an excess of a concentrated solution of sal-ammoniac ridite of ammonium, $6NH^4Cl.Ir^2Cl^6$, is then formed, which is soluble in sal-a whereas the double compounds of chloride of ammonium with the chlorides of platinum-metals (except sesquichloride of rhodium) are insoluble in excess of of ammonium.

The reduction of dichloride of iridium in solution to sesquichloride may b by any of the reducing agents already mentioned (pp. 315, 319), but the most co for analytical purposes is *sulphydric acid*.

When, for example, iridium is to be separated from platinum, both bein form of tetrachlorides, the mixture of these compounds, or rather their dou with chloride of ammonium or potassium, may be treated with a small qu water, and solution of sulphydric acid added by small portions. The reducti iridic chloride then takes place immediately, a green liquid being formed, milky by precipitated sulphur, and coloured brown by sulphide of platinu metal is present in rather large proportion. Iridium is not precipitated from tions as sulphide by sulphydric acid at ordinary temperatures, unless the added in very large excess, and even then the precipitation takes at least The reduction of the iridium to trichloride being complete, sal-ammoniac is excess, and the liquid filtered. The platinum then remains undissolved, iridium passes into the filtrate, and may be reconverted into tetrachloride by nitromuriatic acid, and precipitated as already described.

The same method may serve to separate iridium from osmium, but the s

IRIDIUM, OXIDES OF. Iridium forms four compounds with
IrO, Ir^2O^3, IrO^2, and IrO^3. The *protoxide*, or *Hypo-iridious ox*
little known. It is obtained by precipitating an alkaline hypochloriri
alkali in an atmosphere of carbonic anhydride (p. 323); but on expos
is quickly converted into a higher oxide. (Claus.)

The ***sesquioxide***, or ***Iridious oxide***, Ir^2O^3, was formerly regar
easily formed and most stable of the oxides of iridium; but, accord
has a great tendency to take up oxygen and pass to the state of diox
prepared by gently igniting a mixture of chloriridite of potassium (6
carbonate of sodium in an atmosphere of carbonic anhydride; on trea
with water, the sesquioxide remains in the form of a black powder i
(Claus, Ann. Ch. Pharm. lix. 251). It forms two hydrates, one cont
other 5 at. water. The **trihydrate**, $Ir^2O^3.3H^2O$, is obtained by treat
the olive-green sesquichloride, or one of its double salts, with potash
black precipitate, which, when treated with hydrochloric acid, yields
of olive-green sesquichloride. The **pentahydrate**, $Ir^2O^3.5H^2O$, is ob

time out of contact of air, a dirty yellow precipitate containing Ca^3Ir^2O
(Claus, J. pr. Chem. lxxx. 282; Jahresb. 1860, p. 207.)

The ***dioxide***, or ***Iridic oxide***, IrO^2, is, according to Claus,
prepared and most stable of all the oxides of iridium, and is always
form of a bulky, indigo-coloured hydrate, $Ir^2O^2.2H^2O$, when a solut
the chlorides of iridium or their double salts is boiled with an alkali
retains 3 or 4 per cent. of the alkali. The hydrate may also be obtai
the hydrated sesquioxide in potash and treating the solution with an a
blue precipitate is then formed, which gradually absorbs oxygen fr
assumes an indigo-colour. The hydrate parts with its water when heat
in acids, forming solutions which are dark brown when concentrated
when dilute.

The ***trioxide***, or ***Periridic oxide***, IrO^3, is formed, according
iridium is fused for some time with nitre. The resulting blackish-
solves in water, forming a deep indigo-coloured solution of basic periridi
leaving a black crystalline powder consisting of acid periridiate. Th
washed, is perfectly neutral and tasteless, and dissolves with indigo-
chloric acid, giving off a very large quantity of chlorine. The qu
in it is variable, but the iridium and oxygen (in the acid) constan
proportion of 1 to 3. (Claus, Ann. Ch. Pharm. lix. 249.)

IRIDIUM, OXYGEN-SALTS OF. Iridium, like the other
shows but little tendency to form oxygen-salts. The oxides dissolve
definite salts are obtained in this way. The solution of iridic oxide
has a dark brown colour, which is not modified by potash in the same
of the tetrachloride, neither does it yield any blue precipitate on boilin

$.(2K^2SO^3.IrSO^3.SO^2).12H^2O$ is obtained by heating ium with acid sulphite of potassium till the green evaporating. It forms minium-red crystals, yields with carbonate of potassium in an atmosphere of ed by prolonged heating with acid sulphite of potas-Claus, Ann. Ch. Pharm. cvii. 129.) In a former 4–348) Claus represented this salt by the formula which the protoxide of iridium was supposed to be uric anhydride S^2O^4Cl. The same acid may be ing salts:

by treating the preceding salt with hydrochloric ls, easily soluble, with yellow colour, in water, l crystals contain 5 and 6 per cent. water ($=4HO$), alis slowly decompose the salt, and nitromuriatic to an iridic salt. Its composition might also be $.(2KCl.Ir^2Cl^2)$; but it appears to contain a proto-iridium.

s salt is contained in the mother-liquor of δ, and coloured, viscid mass, which dries up to an amor-ing a yellow powder. It is decomposed by water, is converted into the white salt α. (Claus, Ann. *elin's Hand-book*, vi. 388.)

F. Four of these compounds are described, analo-y precipitating the solutions of the chlorides with *de*, IrS, obtained also by heating either of the is grey or blackish-blue. According to Berzelius, it po-iridious or iridious sulphate; and in sulphide phide of platinum. The *sesquisulphide*, Ir^2S^3, is a soluble in water [? when partially oxidised], and ith nitric acid and sulphide of potassium (Ber-obtained by precipitation, also by igniting chlor-ual weight of sulphur (Vauquelin); by igniting nd an alkaline carbonate, and exhausting the pro-ogg. Ann. lix. 66); and by mixing a solution of alcohol with sulphide of carbon, and leaving the ek. It is then converted into a gelatinous mass, d on a filter, washed with alcohol, then repeatedly ed. The product thus obtained is disulphide of vn powder, which is decomposed by heat, leaving ium according to the temperature to which it is by precipitation behaves with nitric acid and with otosulphide. The *trisulphide*, IrS^3, is obtained by ulphydric acid, but to complete the decomposition, ic acid must be left for a considerable time in a yellow-brown precipitate, which behaves like the id and sulphide of potassium. (Berzelius.)

ONIACAL. *Ammonio-dichloride of iridium, monium*, $N^2H^6Ir''.Cl^2$, is prepared by heating tetra-converted into dichloride, dissolving the brown ammonia, and adding hydrochloric acid in slight arates in the form of a yellow granular preci-oxide corresponding to this chloride has not The *sulphate*, $N^2H^6Ir''.SO^4$, is obtained by heat-nuric acid. It crystallises in large orange-yellow —*Tetrammonio-dichloride of iridium*, $4NH^3.IrCl^2$,

, $N^2H^4\overbrace{(NH^4)^2}Ir''.Cl^2$, is obtained as a white preci-

Digitized by Google

pitate, by boiling the compound, $N^2H^6Ir''.Cl^2$, with excess of ammonia. Treated with moderately strong sulphuric acid, it yields the corresponding sulphate $(N^2H^4(NH^4)^2Ir''.SO^4$ in rhombic prisms; and, by decomposing this salt with nitrate of barium, or the chloride with nitric acid, the nitrate is obtained in yellow needles, which dissolve readily in water, melt when heated, and then suddenly decompose with flame.—*Chloronitrate of ammiridammonium*, $N^2H^4(NH^4)^2Ir''\left\{\begin{matrix}(NO^3)^2\\Cl^2\end{matrix}\right.$, or *Nitrate of ammochloriridammonium*, $N^2H^4(NH^4)^2(IrCl^2).2NO^3$, analogous to Gros' platinum-nitrate, is obtained as a yellowish, crystalline, granular mass, by heating the chloride of iridammonium, $N^2H^6IrCl^2$, with strong nitric acid; when recrystallised from water, it forms shining, yellow, laminar crystals.—*Dichloride of ammiridammonium*, $N^2H^4(NH^4)^2Ir''.Cl^2$, or *Chloride of ammochloriridammonium*, $N^2H^4(NH^4)^2(IrCl^2).Cl^2$, is obtained by treating the last-mentioned salt with hydrochloric acid, in the form of a violet precipitate, which dissolves readily in hot water, and separates from the solution in violet crystals. Nitrate of silver added to the solution throws down only half the chlorine. The nitrate, treated with dilute sulphuric acid, yields the chlorosulphate of ammiridammonium, in delicate greenish, needle-shaped crystals. (Skoblikoff, Ann. Ch. Pharm. lxxxiv. 275.)

The compound $10NH^3.Ir^2Cl^6$, or $\left.\begin{matrix}N^2H^4(NH^4)^2Ir''\\N^2H^2(NH^4)^4Ir''\end{matrix}\right\}Cl^6$, is obtained by mixing a dilute solution of chloriridite of ammonium, $(NH^4)^6Ir^4Cl^{12}$, with excess of ammonia, and leaving the mixture in a well-closed and completely filled bottle for some weeks in a warm place; heating the liquid, which has then acquired a rose colour, to expel the excess of ammonia; neutralising with hydrochloric acid, evaporating to dryness, and treating the greenish-yellow residue with cold water to extract the chloride of ammonium. A light flesh-coloured, finely crystalline powder then remains, which, when dissolved in boiling water acidulated with hydrochloric acid, yields on cooling, a crystalline precipitate of $10NH^3.Ir^2Cl^6$, mixed with trichloride of iridium. This compound, when dissolved in a boiling solution of ammonia, is partially decomposed, with separation of blue hydrated dioxide of iridium; when digested with water and oxide of silver, it yields a rose-coloured alkaline solution of the base $10NH^3.Ir^2O^3$. This solution, saturated with various acids, yields crystalline salts, soluble in water, namely, a *carbonate*, $10NH^3.Ir^2O^3.3H^2CO^3$, as a light flesh-coloured, finely crystalline, alkaline powder; a *nitrate*, $10NH^3.Ir^2O^3.3N^2O^6$, in indistinct, light flesh-coloured, neutral prisms; and a sulphate, $10NH^3.Ir^2O^3.3SO^3$, also neutral and of similar colour. (Claus, *Beiträge zur Geschichte der Platin-metalle*, Dorpat, 1854; Jahresb. 1854, p. 434.)

IRIDOSMINE. *Native iridium, Osmide of Iridium, Osmium-iridium, Iridosmium, Newjanskite, Sisserskite.*—This compound occurs, together with platinum, in the province of Choco in South America, in California, Oregon, Australia, and in the Ural mountains; also in the gold washings on the rivers du Loup and des Plates, Canada. It sometimes constitutes the principal part of platinum ore, especially of that from Katharinenberg, Slatoust, and Kischtin in the Ural. It occurs rarely in hexagonal prisms with replaced basal edges, commonly in irregular grains, flat or round, sometimes in very thin laminæ. It has a metallic lustre, tin-white or light steel-grey colour, and is slightly malleable. Hardness = 6 to 7. Specific gravity = 19·3 to 21·12.

The following are analyses of specimens from different localities:—1. By Thomson (*Gmelin's Handbook*, vi. 425).—2. By Claus (*Beiträge &c.*).—3. By Berzelius (Pogg. Ann. xxxii. 232).—4–8. Deville and Debray (Ann. Ch. Phys. [3] lvi. 385; Jahresb. 1859, p. 767).

Iridosmine has usually been regarded as consisting of definite osmides of iridium (the iridium being more or less replaced by rhodium, ruthenium, and platinum); No. 1 agreeing nearly with the formula Ir^3Os; 2, with IrOs; and 3, with $IrOs^3$. But according to Deville and Debray, it is not a homogeneous substance, and cannot be regarded as a distinct mineral species.

Iridosmine, when heated in the air, gives off osmic acid, with greater facility as it is

Digitized by Google

richer in osmium, and becomes dull. When ignited for some time with nitre alone, or with nitre and caustic potash, it gives off part of the osmium as osmic acid, and forms osmate of potassium, together with iridiate of potassium (p. 314). According to Fischer (Pogg. Ann. xviii. 258) it is more easily decomposed by nitrate of calcium, and according to Deville and Debray (p. 316) by a mixture of peroxide and nitrate of barium. Nitromuriatic acid has scarcely any action upon it. [For the methods of analysing it, see IRIDIUM, pp. 315, 316, 320; also PLATINUM-RESIDUES.]

IRISINE. See CHINOLINE (i. 871).

IRITE. This name was given by Hermann, J. pr. Chem. xxiii. 276) to a black mineral from the Ural, crystallised in regular octahedrons and consisting of the protoxides of iridium, osmium, and iron, combined with the sesquioxides of iron and chromium. According to Claus (*ibid.* lxxx. 285) it is a very variable mixture, consisting chiefly of iridosmine and chrome-iron ore.

IRON. Synonyms: *Eisen; Fer; Ferrum; Mars.* Symbol: Fe. Atomic weight: 56. Equivalents: Fe = 28 (ferrosum); fe = 18⅔ (ferricum).

This metal, although the most abundant of the heavy metals, and most largely employed in the arts, is but little known in a state of absolute chemical purity. The iron met with in commerce always contains carbon, and generally some other foreign substances, altogether varying in amount from 0·5 to nearly 10 per cent. Probably all these admixtures exercise some influence on the characters of the metal; but it appears to be chiefly the amount of carbon contained in iron, which determines the remarkable differences of character presented by the several varieties of metallic iron known as malleable iron, cast iron, and steel.

Pure iron is described as resembling silver in whiteness, capable of receiving a very high polish, extremely tenacious, softer than ordinary malleable iron, and presenting a scaly, conchoïdal, or sometimes crystalline fracture. Specific gravity, after melting 7·8439, in sheet or wire 7·75 to 7·60.

Iron obtained by electrolysis was found to have a specific gravity of 8·1393. Its malleability was not affected by heating to redness and rapid cooling, nor was it in the least degree hardened by this treatment. It was scarcely acted upon by acids at the ordinary temperature; but dissolved with the aid of heat, evolving hydrogen quite free from the peculiar smell observable in the hydrogen evolved during the solution of ordinary iron. (Percy, *Metallurgy*, ii. 2.)

The crystalline form of iron is either the cube, octahedron, or some other form belonging to the regular system.

The different kinds of iron employed in the arts may be comprised under three heads, viz. malleable iron, cast iron, and steel, the latter being to some extent intermediate in its characters between the other two, and combining some of the peculiarities of both. See STEEL.

The difference between these three kinds of iron is, however, by no means absolute, even as regards their characters, but more a difference in the degree in which particular characters are presented. Iron approaching nearest to a state of purity requires a very high temperature for its fusion, while cast iron melts at a comparatively low heat, but, not being sufficiently malleable, it cannot be wrought into any required shape. Malleable iron has a much higher degree of toughness or tenacity than cast iron, which on the other hand is much harder, while steel may be melted and forged, as well as rendered hard or soft at will, or as it is technically termed "tempered," by cooling suddenly or gradually; on account of these varied combinations of qualities, the different kinds of iron have a wide range of applicability to a great diversity of purposes.

Leaving out of consideration for the present all the other substances met with in iron except carbon, it appears that the greater or less approximation to the character of pure iron is so uniformly accompanied by very slight differences in the amount of carbon, that these two circumstances may be regarded as having a very intimate causal connection.

Karsten's observations lead to the conclusion that iron containing 0·65 per cent. carbon, and free from any other substance, becomes so much hardened by plunging it into water, while red-hot, that it may be regarded as steel. When the amount of carbon is as much as 1·4 or 1·5 per cent. the metal presents the maximum combination of tenacity with the capability of hardening by sudden cooling. Increase in the amount of carbon beyond this limit is accompanied by increased hardness, but the tenacity and malleability are less. With 1·75 per cent. carbon, the malleability of the metal is very slight, and with 1·9 per cent. it scarcely admits of being wrought. Iron with 2·3 per cent. carbon presents, when melted and gradually cooled, indications of graphite being separated during the cooling, and the other characters of cast iron, which may contain an amount of carbon varying from this minimum limit up to 5·75 per cent.

These limits, however, are somewhat different when iron contains other substances,

Digitized by Google

as is usually the case: thus, taking as the criterion between malleable iron and steel, the capability of acquiring, by sudden cooling, such a degree of hardness as to give sparks when struck with flint, this is generally found to obtain with iron containing 0·5 per cent. when it also contains small quantities of silicon, sulphur, phosphorus, &c.

Taking as the criterion which distinguishes cast iron from steel, the separation of graphite when the melted metal is slowly cooled, and the want of malleability in the cold, it is found, in like manner, that the relation between these characters and the amount of carbon is not strictly constant, but that it is to some extent modified by the nature and amount of other admixtures, not only by their rendering the metal less malleable, but also by their promoting the tendency to the separation of carbon.

Malleable Iron (*Schmiedeisen; Stabeisen; Fer doux*).—Ordinary malleable iron has a grey colour, which varies in its shade according to the character of the iron, and has sometimes a bluish or blackish tinge.

The specific gr ty varies between 7·3 and 7·9; that of the better kinds generally approximating to the mean of these two values. The specific gravity is affected to some extent by the alteration of internal texture produced mechanically. Thus a bar 4 inches wide and 1 inch thick with a specific gravity = 7·8010 acquired a specific gravity = 7·8621 when rolled out to very thin sheet, and iron of specific gravity 7·7938 acquired a specific gravity = 7·8425 when drawn into very thin wire. (Karsten.)

The specific heat of ordinary malleable iron is 0·113795, and is somewhat higher when the amount of carbon in the metal is large. (Regnault.)

The conducting power for heat is 374·3 compared with gold = 1000. (Despretz.)

The linear and cubical expansion by heat (see HEAT, iii. 68, 71) is less than that of most other metals. The linear expansion for each degree between 100° and 300° C. = $\frac{1}{88\,190}$. (Dulong and Petit.)

An iron bar expands $\frac{3}{560}$ when raised from a red heat to a white heat, and $\frac{7}{560}$ when heated from 20° C. to whiteness. (Rinman.)

The melting point of malleable iron has not been determined with any degree of certainty. It is between the melting point of cast iron and that of platinum, and is estimated at 1550° C. by Pouillet, and at 2000° C. by Scheerer, and there is no doubt that it is higher in proportion as the metal contains less carbon.

Pure iron is attracted by the magnet more powerfully than iron containing carbon, and it may be rendered magnetic; but it does not retain the magnetic condition so long as iron containing some carbon. Ordinary bar iron is also attracted more strongly than steel, and is more easily rendered magnetic, but loses the polar condition much sooner than steel does. It appears therefore that the presence of a certain amount of carbon is in some way necessary for the retention of the magnetic condition by iron. Bars of iron placed vertically or nearly so become, in course of time, magnetic. The magnetic condition of iron is very nearly destroyed by a red heat, and entirely so by exposure to a white heat.

The electric conductivity of iron is much less than that of copper. Taking this as = 100, that of iron is = 20 (Harris), 15·8 (Becquerel), 17·74 (Lenz). Matthiessen considers that the electric conductivity of electro-deposited iron is much higher than that of ordinary malleable iron.

	Conductivity at 0° C.	Percentage decrement in conductivity between 0° and 100° C.	Deduced conductivity of pure iron at 0° C.
Electrotype iron	100	38·3	
Plate iron . .	91·8	36·0	102·7
	72·8	34·1	102·1
	84·6	34·7	99·2

The hardness of malleable iron varies considerably; it is influenced by the presence of foreign substances, and reduced by increase of temperature. It is however but very slightly increased by sudden cooling of the red-hot metal; the less so the smaller the amount of carbon contained in it. A certain amount of carbon seems essential to the hardness of malleable iron. Absolutely pure iron is so soft that it offers but little resistance to friction.

The tenacity of iron also varies widely, and is influenced by the nature and amount of foreign admixture in the metal, as well as by its internal texture, by temperature, and by other conditions. Up to a temperature of 146° C., the tenacity of boiler plate is not sensibly diminished; but at a red heat it is reduced one fourth. The tenacity of good rivet iron at 190° C. is a third greater than at the ordinary temperature; but at a red heat it is reduced to nearly one half. (Fairbairn, *Useful Information for Engineers.*)

(See Kirkaldy, Trans. Instit. of Engineers in Scotland, 1858–9; and *Tensile Strength of Wrought Iron and Steel*, London, 1862.—Fairbairn, Brit. Assoc. Report, 1856.)

The malleability of iron is very considerable, though less than that of silver or gold. It is influenced by the presence of foreign substances which modify the hardness and tenacity, the degree of malleability being apparently determined by the relative hardness and tenacity, and to some extent also by its internal texture. The malleability of iron is increased in proportion as its temperature is raised, inasmuch as it then becomes softer without its tenacity being proportionally lessened. At a red heat it is sufficiently soft to be brought to any required shape by hammering or rolling, and at a white heat it becomes quite pasty, so that separate pieces may be, as it were, kneaded together into one mass; or, as it is termed, *welded*. This capability of being forged and welded, so important as regards the methods by which iron is wrought for various uses, is referable to the wide interval between the temperature at which the metal presents its ordinary degree of hardness, and that at which it becomes liquid; as well as to the fact that, at temperatures far below the melting point, it acquires a soft plastic condition, which is retained in a greater or less degree through a considerable range of temperature.

Among the foreign substances influencing prejudicially the malleability of iron, the chief are sulphur, phosphorus, and silicon. The first communicates to it the character of being brittle while hot, or, as it is called, "red short" in forging. Phosphorus renders iron "cold short," or brittle and weak at the ordinary temperature. Silicon has a similar influence in a higher degree. Manganese seems to be beneficial rather than otherwise as regards the malleability of iron. The malleability of iron is considerably reduced by immersing it while red-hot in cold water, as well as by long continued hammering and by rolling, but it is again restored by heating the metal to redness, and allowing it to cool gradually.

The texture, or molecular structure of iron varies very considerably according to the treatment to which it has been subjected. After being melted, iron is decidedly crystalline or granular, and its fracture presents distinct indications of that condition. By hammering or rolling while hot, it acquires a fibrous or silky texture, becomes more tenacious, less susceptible of true fracture, and capable only of being torn asunder. In the usual method of producing malleable iron, it is not melted, but wrought mechanically while in a kind of doughy condition, and the uniform close fibrous texture which determines the quality of the metal depends much upon the nature of this treatment and the extent to which it is carried.

By hammering while cold, fibrous iron is rendered harder and brittle; when afterwards broken, it presents a granular or crystalline fracture, but opinions differ as to whether this crystalline condition be really a result of the hammering. This is also the case with regard to the influence of long continued pressure, vibration, or concussive action, in affecting the texture of iron, some maintaining that these conditions slowly destroy the fibrous texture, rendering the iron crystalline and thereby weaker. (Rankine, Proceedings of Inst. of Civil Engineers, 1843; Percy, *Metallurgy*, ii. 8.)

Malleable iron undergoes no change in dry air, or in water free from air; but in moist air, or in water containing air, it gradually becomes oxidised or rusted, from the surface inwards, until eventually the entire mass may be converted into oxide. The carbonic acid present in atmospheric air appears to contribute largely to the production of this change. The presence of saline substances in water also facilitates the oxidation of iron; while alkalis, and oily or resinous substances, retard the oxidation. (Mallet, *Action of air and water, &c., upon cast iron, wrought iron, and steel*, Brit. Assoc. Reports, 1838, p. 253; 1840, p. 221.) Contact with more highly electro-positive metals, such as zinc, also hinders the oxidation of iron within a certain distance around the point of contact.

At a temperature about 230° C., iron becomes capable of combining directly with atmospheric oxygen, and the polished surface at first becomes covered with an extremely thin film of magnetic oxide, of a yellow colour which gradually passes into red, blue, and grey. At a red heat this crust of oxide—*forge scale*—becomes thicker, and gradually passes at its outer surface into ferric oxide. At a white heat, iron burns

Digitized by Google

in the air, with production of magnetic oxide, and this combustion may be sustained for some time by directing a blast of air upon the metal.

At a temperature about 360° C. iron decomposes water-vapour, forming magnetic oxide and liberating hydrogen.

Pure iron dissolves completely in moderately dilute acids. Ordinary malleable iron dissolves completely in strong hydrochloric acid: but with dilute acid a carbonaceous residue remains undissolved. In both cases also the hydrogen evolved carries with it carbonaceous vapour, which communicates to it a peculiar smell.

Malleable iron generally contains from 0·25 to 0·5 per cent. carbon; sometimes the amount is much less. The smaller the amount of carbon, the softer is the iron, and

Digitized by Google

portions. This latter difference will be more marked in proportion as the melted metal is more rapidly solidified at the surface. In one instance of iron cast in an iron mould, referred to by Karsten, the following results were obtained:—

	Total quantity of carbon.	Combined carbon.	Graphite.
Cast iron before melting . . .	4·0281 . .	= 0·7812 . .	3·2469
Outer white portion of casting . .	5·0929 . .	= 5·0929	
Inner grey portion of casting . .	3·8047 . .	= 0·6106 . .	3·1941

The main chemical difference between white and grey cast iron consists in the state in which the carbon they contain exists. In specular iron, the whole of the carbon is combined with iron, while in the most characteristic kind of grey cast iron, when solid at least, the greater part of the carbon is merely mixed with the iron, in the state of graphite, and only a portion of it is in a state of combination. Between these two extremes there are a variety of intermediate states in which white and grey cast iron are mixed together in various proportions, constituting what is known as *mottled cast iron* (*halbirtes Gusseisen*; *fonte truitée*).

The hardness and strength of these varieties of cast iron differ considerably; as a rule, the grey is stronger than the white, and this again is harder than the grey. White cast iron is, however, too brittle to be used for structures, except for the purpose of coating the surface of castings with a hard crust or skin, by casting in moulds lined with metal (chill casting). (Rankine, *Civil Engineering*, p. 499.)

The tenacity of cast iron is very much less than that of malleable iron; but its capability of resisting crushing force is very much greater.

Kind of iron.	Direct Tenacity.	Resistance to direct crushing.	Modulus of rupture of square bars.	Modulus of Elasticity.
	In pounds per square inch.			
Cold blast . .	from 12,694 to 18,855	56,455 102,408	36,693 39,609	14,000,000 17,036,000
Hot blast . .	from 13,434 to 23,468	72,193 104,881	29,889 43,497	11,539,000 22,733,000
Toughened cast iron	from 23,461 to 25,764	129,876 119,457		

The strength of cast iron is increased by remelting, but reduced when the melting is repeated several times. At very low temperatures it becomes more brittle and weaker. (Fairbairn and Hodgkinson, *Report on the Application of Iron to Railway Structures*, p. 265.)

The specific heat of specular iron = 0·12983, that of ordinary white cast iron = 0·12728. (Regnault.)

The linear expansion of cast iron by heat is greater than that of malleable iron, amounting to $\frac{7}{5000}$ between 20° and 560° C. (red heat), and $\frac{12}{560}$ between 20° and a white heat. (Rinman.)

Pieces of cold cast iron thrown into the melted metal sink to the bottom; but when they have a temperature near the melting point, they float on the surface of the melted metal. Hence it would appear that some degree of contraction takes place in the passage from the solid to the liquid state. This character of cast iron is important as regards its application to casting: for the increment of bulk attending solidification ensures the perfect filling of the moulds at that moment, and the production of sharp, well-defined castings. But the greatest amount of expansion or contraction takes place just below the melting point. On account of this contraction between a temperature near the melting point and the ordinary atmospheric temperature, it is necessary to make the moulds for castings proportionately larger than the castings are required to be. The contraction of grey cast iron amounts to about 1 per cent.; that of white cast iron is from 2 to 2·5 per cent. of the linear dimensions. The allowance generally made for this "shrinkage" in casting is $\frac{1}{96}$ or one eighth of an inch in a foot. Cast iron also undergoes a permanent increase of bulk under the long-continued influence of heat. (Percy, *Metallurgy*, ii. 872.)

White cast iron exposed to oxidising influences at the ordinary temperature, rusts much more slowly than grey cast iron, and this again, provided it does not contain much sulphur or other readily oxidisable substances, more slowly than malleable iron. Specular iron is but very little liable to oxidation.

At an elevated temperature, grey cast iron becomes coloured by oxidation sooner than malleable iron; white cast iron on the contrary becomes coloured even sooner

Digitized by Google

than steel. When cast iron is heated to redness in the air, the carbon it contains is first oxidised and the metal rendered more or less malleable; then a crust of magnetic oxide is formed at the surface and gradually increases in thickness as in the case of malleable iron. Grey cast iron is most slowly oxidised in this way, and becomes porous and friable after abstraction of its carbon. White cast iron is decarbonised more rapidly, and acquires a malleable steely character. Upon this fact is based the manufacture of malleable cast iron, which consists in heating to redness the castings, while imbedded in powdered chalk, charcoal, or oxide of iron, so as to be partially protected from the oxidising influence of the air.

Cast iron melted in contact with air becomes covered with a crust of oxide, and by removing this crust from time to time, it may be entirely converted into oxide. If the crust is allowed to remain in contact with the melted metal, this gradually becomes decarbonised, steely and less fusible. White cast iron heated in contact with air till it assumes the pasty condition, is decarbonised much more rapidly than by mere heating to redness, and passes from the steely condition to that of pure iron, without so great a degree of oxidation as takes place when the metal is melted. The most important method of manufacturing malleable iron is based upon this fact (puddling).

Cast iron melted under soda, potash, lime, or magnesia carbonates, is gradually decarbonised, and may be wholly converted into malleable iron, if the heat be raised as the iron becomes less fusible.

Atmospheric air forced into melted cast iron oxidises the carbon and silicon, as well as part of the iron, and converts the remainder into malleable iron. The temperature produced in this way is sufficiently high to determine the fusion of the wholly decarbonised iron. (See STEEL.)

White cast iron heated with concentrated hydrochloric acid is entirely dissolved; but grey cast iron, treated in the same way, leaves a residuum of graphite. In both cases the combined carbon enters into combination with a portion of the nascent hydrogen eliminated by the solution of the iron, forming volatile oily hydrocarbons, the vapour of which communicates a peculiar smell to the gas evolved. This oily substance, which appears to be of a nature analogous to petroleum, also collects as a thin film on the surface of the acid solution.

The action of dilute hydrochloric acid upon cast iron is somewhat different. Specular iron is acted upon very slowly at the ordinary temperature, but with the aid of heat, both it and grey cast iron are readily dissolved. The hydrogen evolved has the characteristic smell, but the amount of the hydrocarbons formed appears to be smaller than when concentrated acid is employed. White cast iron leaves a bulky dark-brown carbonaceous residue, which is soluble in potash, and, when washed and dried is very readily combustible, leaving a black residue containing silica (Daniell, Journal of Science and the Arts, ii. 278). Grey cast iron leaves a residue consisting partly of graphite, partly of a carbonaceous substance similar to that obtainable from white cast iron, and, partly of a black carbonaceous substance which is magnetic, takes fire by contact with the air, and leaves when burnt a residue of ferric oxide.

Cast iron is slowly acted upon by sea-water. Cannon balls that had been lying in the sea off the coast of Normandy since 1692, were found to have lost two-thirds of their original weight, contained no metallic iron, and were converted into a substance that could be cut with a knife (Deslongchamps, J. Chim. méd. xiii. 89). Cannon balls taken from vessels sunk fifty years before, near Carlscrona, were found to be partly converted into a grey porous graphite substance, which after exposure to the air for a quarter of an hour, became so heated that the adherent water was converted into steam (Berzelius, *Gmelin's Handbook*, v. 218). The substance remaining after the action of sea-water, appears to be similar to that remaining, mixed with graphite and the bulky carbonaceous residue, after dissolving grey cast iron by dilute hydrochloric acid, and which Karsten regards as a compound of iron with three equivalents of carbon. Berzelius considered this solution of cast iron by sea-water to be due to the conjoint action of carbonic acid and oxygen. The solution of cast iron takes place at places where it is exposed to the combined influence of fresh water and sea-water by tides more rapidly than in sea-water. (Mallet, *op. cit.*)

The solution of cast iron takes place at places where it is exposed to the combined influence of fresh water and sea water, by tides more rapidly than in sea water.

The maximum amount of carbon in cast iron is met with in specular iron, varying from 5·75 to 5·24 per cent. Bromeis and Percy consider that the manganese present, so far as is yet known, in all specular iron containing as much as 5 per cent. carbon, is in some way essential to this high proportion of combined carbon.

In grey cast iron the amount of carbon varies, as a general rule, between 2 and 4·65 per cent.; in white cast iron it is from 3·5 to 5·75 per cent; but the difference between white and grey cast iron is more intimately connected with the state in which the carbon exists, than with the amount of this substance.

Besides iron and carbon, cast iron always contains other substances, as ind the above analyses, especially silicon, sulphur, phosphorus, manganese, arsen They probably exist, in combination with equivalent quantities of iron, a sulphide, phosphide, &c., and some of them appear to exercise considerable upon the quality and characters of the metal, although the mode in which cised is but very partially understood, and the very nature of that influence cases dubious.

Silicon is almost always present in cast iron to some extent, originating deoxidation of silica in the process of smelting. The amount varies very r white cast iron it is generally from 0·1 to 0·5 per cent. In grey cast iron the much greater, and is seldom less than 0·5 per cent., sometimes exceeding even Karsten found 3·46 per cent. to be the maximum amount. The greater silicon in grey cast iron is considered to be due to the higher temperature a is produced. Iron produced with hot blast contains more silicon than that with cold blast.

It is generally considered that, within the ordinary limits as to the amount in cast iron, this substance does not exercise any prejudicial influence upon t of the metal; but, in the conversion of cast iron into malleable iron, the sil be as much as possible separated, since it is very detrimental to malleabl regards its tenacity. The greater the amount of silicon in pig iron, the great the waste incurred in its conversion into malleable iron by the puddling oper

Sulphur is almost always present in cast iron, but sometimes the amount i that it can hardly be estimated. It probably never reaches 0·5 per cent. in iron. Iron smelted with mineral fuel always contains more sulphur than tha with charcoal, in consequence of the sulphur contained in the coal or coke be ferred to the iron. The presence of sulphur in cast iron renders it more fu also more liable to solidify sooner when slightly cooled below the melting p to become quite viscid while still red-hot.

When specular iron is melted with sulphur, carbon separates and collects upo face of the melted mass in the form of graphite, which differs from ordinary in having no lustre. Grey cast iron melted with sulphur is converted into iron, containing a greater amount of carbon than the original grey iron, as the following results obtained by Karsten (*Eisenhüttenkunde*, i. 583):

	The grey cast iron contained in 100 pts.	The resulting wh contained in 10
Combined carbon . . .	0·6253	5·4878
Graphite	3·3119	
Sulphur.	0·0286	0·4464

Hence it would appear that sulphur displaces carbon existing in co with iron, but that up to a certain point, the carbon so displaced from co with one portion of the iron, enters into combination with another portion more can be taken up. The presence of sulphur in cast iron appears th determine the existence of the carbon in the state of combination with the thus to be conducive to the production of white cast iron. (Janoyer, Mines, 1851, iv. 20; Weston, *Percy's Metallurgy*, ii. 135.)

Phosphorus is frequently present in cast iron, sometimes to the extent of cent. When amounting to more than 0·5 per cent., it renders the iron brittle fusible, very liquid when melted, and capable of remaining longer in the liq Within certain limits, therefore, the presence of phosphorus in iron intended f is advantageous rather than otherwise.

Nitrogen.—It appears that cast iron sometimes contains a minute amount of and that it has a considerable influence on the character of the metal. S estimated the nitrogen in several kinds of cast iron as follows (Precht Encyklop. 1847, xv. 364; Phil. Mag. 1840, xvi. 44):

White cast iron (Maesteg, South Wales) . . .	0·764 per ce
Grey cast iron (Creusot, France)	0·720 „
Specular iron	1·200 „

Marchand's experiments led him to doubt the existence of nitrogen in and to infer that if it were present, it never amounted to 0·02 per cent., and indications of nitrogen obtained by analysis were generally referable to abso atmospheric nitrogen by the iron, and formation of cyanogen during the ana

Bouis (Compt. rend., 1861, lii. 1195) on the contrary, considers that nitroge present in cast iron, and has estimated the amount in a sample of very hard

inches broad in mica slate (Shepard). This specimen contained 91·8 per cent. iron iron and 7 per cent. carbon. It is said to be mixed with the granular platinum of South America (John), and disseminated through some basaltic rocks (Andrews), also in the auriferous sand of Oláphian (Molnar). Native iron containing 6 per cent. of silicon and a little sulphur is said to have been found with galena, in the lodes at Leadhills, and in volcanic scoriæ at Graveniére in Auvergne.

2. *Meteoric iron* is met with, both as large compact masses, and as grains and splinters disseminated through earthy meteorites. Its colour is somewhat like that of platinum, and it is characterised by always containing nickel, sometimes also cobalt, copper, chromium and tin. The masses of meteoric iron found in South America and Siberia, and estimated to weigh several tons, are among the most remarkable that are known. Meteoric iron almost always contains particles of iron sulphide mixed with it, apparently neither magnetic nor ordinary pyrites. (Rammelsberg, Pogg. Ann. 1849, lxxiv. 442.)

Iron ores. Compounds of iron occur native in great numbers as minerals, and very widely distributed; there are indeed few natural bodies in which iron is not present to some extent; it exists in the ashes of most plants (see i. 417, ii. 680), and appears to be an essential constituent of the blood of animals (see *ante*, p. 2). Of the native compounds containing iron in large proportion, those which occur in greatest abundance are the oxides, disulphide, carbonate, phosphate, titanate, and silicate. But for the extraction of the metal the only minerals that are suitable are the several oxides and the carbonate, all of which occur as large masses, of a greater or less degree of purity, being generally mixed with varying amounts of siliceous or earthy substances, and smaller quantities of various other minerals. The most important varieties of these ores of iron are the following:—

Native magnetic oxide, Magnetic iron-ore; Magneteisen; Oxyde magnetique.—This is the richest of the ores of iron available for smelting; in its purest state it contains 72·41 per cent. iron. It is black and generally has a metallic lustre, and occurs both crystalline, granular and compact or even earthy, at well as in the state of sand. It exists abundantly in many localities as beds or veins, and sometimes forming entire mountain masses, associated with volcanic or schistose rocks, and chiefly in Norway, Sweden, Siberia, and North America. It is sometimes largely mixed with pyrites and other sulphuretted minerals. In this country magnetic iron-ore occurs in the West of England and at Rosedale in Yorkshire.

The mineral known as *Franklinite* appears to be a variety of magnetic iron ore in which ferrous oxide is replaced by zinc oxide.

British deposits of hæmatite are in Cumberland and

Digitized by Google

Lancashire, the Isle of Man, Devonshire and Cornwall. On the Continent it occurs chiefly in the Hartz, Silesia, the Austrian provinces, and in Norway. A peculiar oolitic hæmatite occurs in the neighbourhood of Liége.

Red ochre is an earthy variety of ferric oxide containing a large admixture of clay.

Specular iron ore; Eisenglanz; *Fer speculaire.*—This also consists of anhydrous ferric oxide in a crystallised form. Its colour is iron grey or almost black. Specific gravity 4·8 to 5·3. The crystals of this mineral belong to the hexagonal system, R.oR and sometimes $R.\frac{4}{3}P^2.\frac{4}{3}R$. It occurs chiefly in schistose rocks, in Norway, the Erzgebirge, in Russia, and several parts of the South of Europe, the most extensive deposit being that in Elba, which has been worked upwards of 3,000 years.

Specular iron ore often contains titanium, either in the form of rutile, or combined with the ferric oxide constituting ilmenite. This was formerly considered prejudicial to the ore; but quite recently it has been stated that the presence of titanium in iron ores, contributes in some way, not yet understood, to the production of good iron.

Native hydrated ferric oxide; Brown iron ore; Braunciseners; hematite brun.—This ore consists essentially of hydrated ferric oxide, which in the pure state contains 59·89 per cent. of iron and 14·44 per cent. combined water. It is sometimes indistinctly crystalline or fibrous; but more generally compact or earthy, and of various shades of colour from blackish-brown to yellowish-brown. This ore frequently contains a considerable amount of manganese, and a more or less considerable admixture of foreign earthy substances. It occurs abundantly in the Forest of Dean in Gloucestershire, in several parts of Devonshire and Northamptonshire, and Lincolnshire, as well as in Weardale, Durham, where it has originated chiefly by the alteration of spathic iron ore. On the Continent it is very abundant, and is one of the principal ores smelted in France and Germany.

A variety of this mineral occurs in many places under the name of bog iron ore (*Sumpferz; minerai des marais*), which has apparently been formed by deposition from ferruginous water under the influence of living organisms. Some kinds of this ore furnish very good iron—for instance, the lake ores of Sweden and Lower Canada; but generally it contains so large an amount of phosphorus as to be useless for smelting.

Yellow ochre is an argillaceous variety of hydrated ferric oxide containing more combined water than brown iron ore, and basic sulphate; sometimes also basic silicate, phosphate, and arsenate.

Spathic iron ore generally contains a considerable amount of manganese and small quantities of lime and magnesia, and is sometimes associated with lead and copper ores, quartz, fluor-spar, calcspar, heavy spar, &c., but is frequently quite free from any admixture of impurities that would be prejudicial to the iron made from it.

Ferrous carbonate mixed with clay often occurs with beds of coal, in sedimentary rocks, and is known under the name of argillaceous, sphærosiderite, or clay iron ore. It is compact and earthy; of various shades of grey and brown, or sometimes quite black, owing to an admixture of carbonaceous substance, and occurs in lenticular masses or nodules. This ore is generally very abundant in the coal measures; but in some instances it is almost wholly wanting in those rocks, as for instance in the coal fields of Northumberland, Durham, Lancashire, and Belgium. The principal localities where it is worked in this country are the coal fields of Scotland, Staffordshire, Shropshire and Wales.

It is found to some extent in France and Germany, and abundantly in America, but is not worked there.

Clay iron ore also occurs abundantly in strata belonging to the Lias, as well as in the Oolite and Tertiary series of rocks, sometimes partially or wholly converted into brown iron ore by atmospheric oxidation. This ore is now largely worked in the Cleveland district in Yorkshire.

Both clay iron ore and carbonaceous iron ore are frequently accompanied by admixtures of metalliferous, sulphuretted, arsenical, and phosphatic minerals, sometimes in such amount as to detract from their value for smelting purposes; but generally they are sufficiently pure to furnish iron of good quality. Some kinds of the ore known as "coal brass" also contain a considerable amount of ferrous carbonate, though they were disregarded as iron ores, until attention was directed to their composition in 1853 by Messrs. Price and Nicholson.

Native iron Sulphides occur very frequently and in great abundance in some places. Of late years these minerals have been much used as a source of sulphur, and are largely imported from Spain and Norway for that purpose. The principal varieties are:

1. *Iron pyrites* (*Eisenkies; pyrite*), which has a yellow colour and metallic lustre. Specific gravity 4·9 to 5·1. It occurs crystalline, granular and compact, frequently disseminated through other minerals. In its purest state it contains 53·33 per cent. iron, and 46·67 per cent. sulphur.

2. *White iron pyrites* (*Strahlkies*; *pyrene*), is a variety of iron pyrites of a white colour; it is also of frequent occurrence.

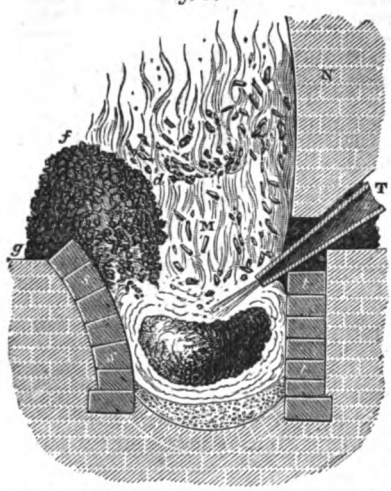
3. *Magnetic pyrites* (*Magnetkies; pyrite magnetique*), has a bronze colour with metallic lustre, and is slightly magnetic. Specific gravity 4·5 to 4·7. It occurs both crystalline or granular, and compact. In its purest state it contains 60·49 per cent. iron, and 39·51 per cent. sulphur.

4. *Arsenical pyrites* (*Mispickel; Arsenkies; fer arsenical*), has a steel grey colour, and metallic lustre. Specific gravity 6 to 6·2. It occurs in the same states as iron pyrites, frequently associated with tin ores, and contains 34·35 per cent. iron, 10·96 per cent. sulphur, and 56·79 arsenic. This mineral frequently contains a considerable amount of silver. Both it and the other varieties of iron pyrites sometimes contain gold, and varying proportions of other metallic sulphides, especially copper pyrites, with which they are frequently associated.

The residue left after separating sulphur from iron pyrites by roasting, is smelted to extract the copper it contains; and attempts are being made to use it also for obtaining the iron from it.

Of other native compounds of iron that occur in large quantities, the most important are the *chromate* (see CHROME IRON ORE, i. 939); the *titanates iserine*, and *ilmenite* (see TITANATES); the *tungstate* (see WOLFRAM); the *silicates* (see GREEN EARTH, ii. 944, and SILICATES); the *ferrous* and *ferric phosphates*. (See PHOSPHATES.)

Preparation.—1. Pure iron may be obtained by heating pure ferric oxide in a current of hydrogen gas. If the reduction be effected at the lowest possible temperature, the iron is obtained in the state of a grey powder which is pyrophoric, and takes fire on contact with atmospheric air, being converted into ferric oxide. At a strong red heat the metal is obtained in a spongy state and is less readily oxidised.



Digitized by Google

2. A mixture of iron wire or iron filings, with one-fourth part of magnetic placed in a closely covered crucible, under a layer of powdered glass, free from metallic oxides, and exposed to a white heat in a smith's forge, yields a button containing only mere traces of carbon or other impurities.

Manufacture on the large scale.—Malleable iron may be obtained directly fr ores by heating them with charcoal under the influence of a blast of air. Fo malleable iron was obtained by this method exclusively, but it is now practised only in Sardinia, the Pyrenees, India, some parts of America, Africa, and other c where metallurgic art is less advanced than in the great iron-producing dist Europe.

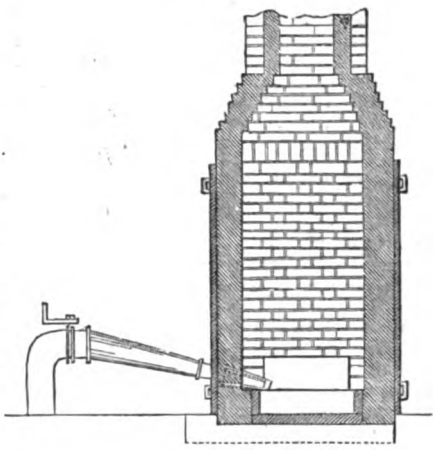
1. *Production of malleable iron direct from the ore.*—This is chiefly practi cording to what is termed the Catalan method. It consists in heating the ore with a charcoal fire urged by a blast, and in a manner very similar in its character, to that adopted in working a smith's forge. The most importan several arrangements for this operation, comprised collectively under the term " ery " (*Luppenfeuer, forge Catalan*), is the *hearth* (*Heerd; creuset*), which is cubical chamber built of stone, and lined with blocks of iron, *s*, *s*, *t*, *t*, at t and front. It is placed against a wall N, N, through which the tuyere, T blowing machine projects, as shown in *fig.* 573. The ore to be reduced is broken the size of a nut, and is placed aga front of the hearth, *s*, *s*, while the ing space M, between it and the *t*, is filled with charcoal, and w hearth is filled in this way, the up of the heap of ore forms a ridge a the surface *f g*, being covered with of closely packed charcoal dust (*d* The fire is then urged by the blast ore becomes gradually deoxidise the gangue or earthy substance c in the ore, combines with a portio rous oxide, forming a fusible silice which collects at the bottom of the Fresh charcoal, and the finely divi are constantly supplied to the fir while, and eventually the de mineral sinks down, in the state c able iron, to the bottom of the where a workman kneads toget fragments into a spongy mass, v taken out of the fire, and render by hammering while still red-hot, unite the metallic particles, and it drawn out into bars under a forge h

Fig. 573.

Only the richer kinds of ore can be treated in this way, and it always i the waste of a large portion of the iron, which escapes reduction, and by into combination with the siliceous and earthy portions of the ore, forms consisting chiefly of ferrous silicate. In the extraction of iron by this method, th tion is effected, perhaps entirely, by carbonic oxide, and the carburation of the such an extent as to determine the production of cast iron, is prevented by the an adequately high temperature.

2. *Indirect process.*—The production of malleable iron is now for the mo effected by operating upon cast iron so as to deprive it of the greater part of the and silicon it contains, and at the same time to separate other admixtures tha be prejudicial to the quality of malleable iron. This operation is conducted ways, the one termed the charcoal finery, the other puddling. Both cons partial oxidisation of the cast iron, and production of a fusible ferrous silicate reacts upon the carburet of iron and determines the oxidation of the greater the carbon and other substances contained in the cast iron.

The main distinction between these two modes of operating is that, in the c charcoal is employed in contact with the cast iron; while, in the other, coal is a reverberatory furnace, so that the iron is acted upon in a separate chamber actual contact with the fuel, but only by the flame and heated gases produced combustion.



White cast iron containing a small amount of carbon is most suitable for con into malleable iron, because it does not melt so readily at a moderate heat and so liquid when melted as grey cast iron, but softens before melting and rema

Digitized by Google

some length of time in a viscous condition, which admits of its presenting a greater surface to the action of oxidising agents when stirred about. Its carbon is also more easily oxidised than the graphite of grey cast iron. When therefore grey cast iron has to be converted into malleable iron, it is in the first instance converted into white iron by a preliminary melting in the running-out fire (p. 349).

The production of malleable iron by the charcoal-finery, is practised in different places with a great number of minute variations, determined partly by the nature of the pig iron operated upon, partly by less important circumstances.

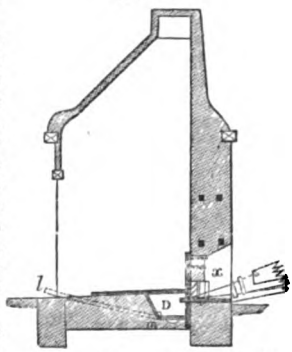


Fig. 574.

The charcoal-finery employed in Wales, and some other parts of the country, for manufacturing the sheet iron used for tin plates, which requires to be of very good quality, is represented in section by *fig.* 574. It consists of a quadrangular hearth lined with cast iron plates enclosed within brick walls and furnished with a blast apparatus. About 2 cwt. of pig iron, melted with coke in a similar kind of hearth, called a *melting finery*, is run into the hearth, covered with charcoal and stirred about, while the fire is urged by a blast of air until the iron becomes sufficiently decarburised to be malleable. Then it is collected in a *lump* (*Luppe; loupe*) at the end of an iron bar, and removed from the hearth for the purpose of being hammered into a prismatic slab about 2 inches thick. This is broken into pieces of about 25 lbs. each, called *stamps* (*schirbel; lopins*). About three of these stamps are piled upon the flattened end of an iron bar termed the *staff* or *portal*, and raised to a welding heat in a kind of reverberatory furnace termed the *hollow fire*, and again hammered into a slab about 3 inches thick, which is passed between rollers until it forms a sheet of the requisite thickness.

In Sweden the greater part of the best iron is made in a very similar manner, except that there, as well as in Germany and other parts of the Continent, the pig iron is melted in the same hearth in which it is converted into malleable iron. An ordinary form of the hearth employed is represented by *fig.* 575.

Fig. 575.

The pig iron is melted above the tuyere, so that it may not be exposed to the blast until it has become liquid, and the blast is regulated so as to retain the metal on the hearth in a proper state of fusion; the blast is then stopped, the slag run off, the iron raised off the hearth, and placed on the top of a fresh supply of charcoal, after which it is again melted. When the decarburation has advanced far enough, which may be judged of by the consistence of the metal, it is again raised up, covered with charcoal, subjected to a strong welding heat to melt away the slag, and then hammered out to a short bar, which is cut into pieces that are again welded together, and drawn out into bars under a hammer.

In order to appreciate the chemical nature of the process that takes place in the charcoal-finery, it is necessary to consider the composition of the slags. They consist essentially of silica and ferrous oxide, but may be divided into two classes, viz. poor slag (*Rohschlacke*) and rich slag (*Gaarschlacke*).

The poor slag is formed during the first melting of the pig iron and the earlier stage of the operation. It consists essentially of ferrous silicate. It is very liquid and solidifies rapidly, is of a blackish-grey colour with metallic lustre, crystalline, frequently variegated, and sometimes porous. The crystals have the form of olivine or iron chrysolite, and the composition of the slag approximates to that of this mineral.

The rich slag is formed during the latter stage of the operation. It is less liquid, and solidifies less quickly than the poor slag. It forms an agglutinated mass; is heavier, of a grey colour, and has a compact fracture. Its composition varies much, and the amount of iron is greatest in that formed at the end of the operation.

In the charcoal-finery process, the separation of the carbon, silicon, phosphorus, and manganese from pig iron is effected by the oxidation of these substances, partly by the blast and partly by the ferrous oxide contained in the slag, formed at the end of the operation.

Cast iron melted with ferric oxide yields carbonic oxide and iron. Iron containing silicon, when heated with iron oxides, yields ferrous silicate. The ferrous silicate constituting poor slag is not reduced, either by pig iron or by carbon, at a red heat; it is only at a very high temperature that there is a reaction between the carbon and ferrous oxide, with elimination of iron. The more highly basic ferrous silicates, constituting rich

slag, on the contrary, are decomposed, even at a red heat, by pig iron, in such a manner that the excess of ferrous oxide is reduced, and a less basic ferrous silicate remains.

During the first stage of the process, the silicon of the iron, together with the oxidised iron, and any sand that may be present, contribute to the formation of poor slag; but as the oxidation of the iron continues, the slag gradually becomes richer in iron, and serves to a great extent as the medium by which the action of atmospheric oxygen upon the pig iron is exercised. Phosphoric acid and manganese also pass into the slag. The conversion of pig iron in this way must not be carried on too rapidly,

is melted, it begins to swell and heave as if boiling, while jets of blue flame issue fro

Fig. 579.

all parts of the mass. This is due to the formation carbonic oxide by the reaction of the carbon in t metal with the ferruginous oxides present. As this r action progresses, the iron becomes pasty, and in co sequence of the oxidation of the silicon contained the iron, and the formation of ferrous silicate, a liqu slag separates from it, and collects round the metal the hearth, or flows away towards the floss *k*. Wh the separation of carbon from the metal has advanc to some considerable extent, the oxidising action the atmosphere in the working chamber is lessened lowering the damper and keeping the iron surround by highly carbonaceous or smoky gas. When the iron has become so far decarb rised as to be malleable, or as it is termed "come to nature," it is gathered together a worked into several lumps with an iron bar, ready to be removed from the furnace.

A modified form of this operation is adopted at some works, under the name of "pi boiling." The furnace used for this purpose is constructed much in the same way the puddling furnace, except that for "pig-boiling" the hearth is much deeper a more pan-shaped than in the puddling furnace. The hearth is also covered with thick layer of red iron ore, or roasted slag from the puddling furnace, and the deca buration of the pig iron is in this case effected probably more by the action of oxidis compounds of iron than by the direct action of atmospheric oxygen.

For detailed descriptions and drawings of the furnaces and machinery used in th manufacture of iron, see Truran, *Iron Manufactures of Great Britain*, London, 186

The presence of sulphur or of some metals, such as zinc, lead, and copper in the p iron, retards the conversion into malleable iron, and in the case of pig iron th becomes very liquid when melted, is more difficult to bring it into a plastic conditi than when it has the viscid character which good white cast iron, containing a sma amount of carbon and a little sulphur, presents when melted. In puddling sulphu iron, there may be a very large waste, due to oxidation of the metal, in consequence the greater time occupied in performing the last stage of the operation. It is th opinion of some that the presence of a certain amount of phosphorus in sulphury iro facilitates its working into balls.

The reactions that take place in puddling are essentially the same as those whic take place in the charcoal refinery. Under the influence of the free oxygen in th atmosphere of the working chamber, a portion of the iron is oxidised, and at the sam time the manganese, silicon, carbon, sulphur, and phosphorus present in the iron, a also oxidised, either by the direct action of air, or through the medium of the metall oxides added to the pig iron, or formed during the process, the result being the pr duction of a slag or cinder, consisting of ferrous and manganous silicates, and magnet oxide, and containing the other earthy impurities present in the iron operated upon, well as part of the sulphur and phosphorus, the one probably in state of sulphide, th other as phosphate. This will be evident from the following analyses of these slags.

The elimination of sulphur and phosphorus from pig iron appears to be alway

Digitized by Google

ed with oxidation of the iron in a degree proportionate to the quantity of those nces separated from the metal. Consequently, in order that the waste of metal curred in producing malleable iron of good quality may not exceed such a limit ld be tolerable in practice, it is essential that the amount of those substances pig iron operated upon should not be large. The smaller the amount of r and phosphorus in the pig iron, the easier is its conversion into good mal- ron, and so far as the separation of those substances is concerned, the smaller waste experienced in this operation.

manganese present in pig iron appears to be always separated almost entirely manufacture of malleable iron. The presence of manganese in pig iron appears cise, in some way not fully understood, a beneficial influence upon the quality nalleable iron made from it by the operation of puddling. Experiments recently y Caron (Compt. rend. xlvi. 828) appear to show that sulphur may be sepa- rom pig iron by the influence of manganese during the decarbonisation, but that orus is not separable in the same way. He operated upon iron containing 1·15 t. of sulphur. By melting it three times without any admixture, the amount hur was reduced to 0·96 per cent; but by adding to it 6 per cent. metallic nese, and by melting three times with access of air, the amount of sulphur was l to 0·8 per cent. The same iron melted with 10 per cent. ferric oxide showed a on in the amount of sulphur from 1·15 to 1·08 per cent., and by melting it with 10 t. ferric oxide and 6 per cent. manganese, the sulphur was reduced to 0·07 per cent.

separation of silicon from pig iron in puddling, as in other modes of producing ble iron, takes place very readily under the influence of oxidising conditions, rmation of ferrous silicate; and the chief importance attaching to its presence in n employed for that purpose, relates more to the amount of malleable iron obtain- an to any special difficulty in the elimination of silicon. In the ferrous silicate ating the slag of the puddling furnace, there is three and a half times as much silicon; so that, if both the silica and the oxide of iron it contains originate he oxidation of the pig iron operated upon, the waste of iron will be very con- le when the amount of silicon in the pig iron is large. Under the supposition e slag is derived wholly from the metal by oxidation, the puddling of pig iron ning 5 per cent. of silicon would be attended with a waste of 15 per cent. of iron this cause alone, independently of that resulting from the separation of carbon, and other substances. Hence it is very desirable that the amount of silicon in n intended for conversion into malleable iron should not be large.

nat modification of the method of producing malleable iron known as "boiling," iron does not undergo any preliminary treatment, and the furnace is sometimes d with the liquid metal run direct from the smelting furnace, so as to save the quisite for remelting it. But in puddling, the practice is generally to submit the n beforehand to an operation known as *refining* (*Feinen; mazéage*), which con- melting the pig iron, in contact with coke and with the aid of an air-blast, in h similar to a charcoal finery, but larger, and termed a *refinery* or *running-out einheerd; feu de finerie*). This operation, which, in fact, corresponds to the first g of the pig iron under the blast in the charcoal-finery, has the effect of partially onising the iron, and of removing from it the greater part of the silicon. At ne time grey pig iron is brought into the condition of white cast iron, which is uitable for conversion into malleable iron by puddling. This change is facilitated denly cooling the metal with water as it runs from the hearth. The composition ed iron, or, as it is technically termed "*metal*" (*Feinesen; fine-metal*), and the that takes place in the process, are shown by the analyses below.

The refinery or running-out fire, represented by *fig.* 580, consists of a rectangular hearth H about 2 feet deep, and rather longer than it is wide. It is lined with cast-iron plates constructed so as to admit of being cooled by water circulating through them, and has three blast tuyeres *t*, *t* supplying hot air on each side. The chimney C is supported upon iron columns, and the spaces between them are closed with cast-iron plates. (See Truran, *op. cit.*, p. 193, *et seq.*)

Fig. 580.

A quantity of coke is put into the hearth, and after the fire has been sufficiently raised, about one or two tons of pig iron is placed on the top, covered with coke, and the fire urged by the blast until the whole of the metal has melted and run down into the hearth, where, under the oxidising influence of the blast, the carbon and silicon it contains are oxidised, and a slag is formed which floats on the surface of the metal. Fresh coke is added, meanwhile, and the heat kept up until the action has advanced sufficiently far. A hole level with the bottom of the hearth is then opened, and the melted metal run into a cast-iron mould B cooled externally by water; and a quantity of water is thrown upon it in order to cool it suddenly and to render the slag discharged from the hearth with it, more easily separable. Sometimes the charge of iron is run into the refinery direct from the blast furnace, and in some cases a quantity of

Fig. 581.

hammer-scale or the slag from previous operations, is added to the charge, in order to facilitate the process of purification by which the silicon and other impurities are separated.

The slag produced in the operation of refining is vitreous, dark-coloured, black or bluish. It consists essentially of ferrous silicate, and generally contains the greater

lifted by the wipers *b*, *b*, *b* of the cam-wheel *a*, and, as that revolves, the hammer is let fall, at the rate of 70 or 80 strokes a minute, upon the anvil *c*, where the puddle-ball is placed. The *steam-hammer* (*Dampfhammer; marteau pilon*), consists of a block of iron, weighing several tons, attached to the piston of a steam-engine fixed above it, by which it may be lifted vertically in guides fitted to the frame work, and let fall upon the ball placed on an anvil.

The machines employed for compressing puddle-balls are of various forms, and are termed *squeezers* (*Quetscher; presse à charnière*). One of the most usual kinds, represented by *fig.* 583, consists of a lever, worked upon a fulcrum at the centre, by a crank

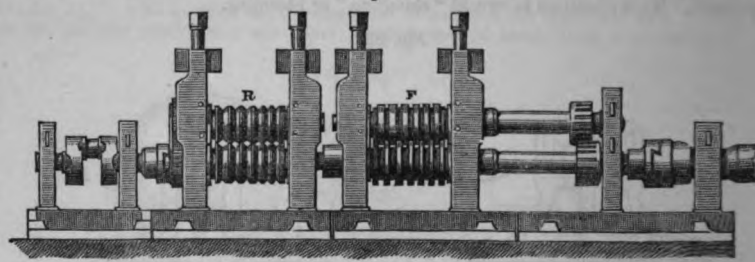

Fig. 583.

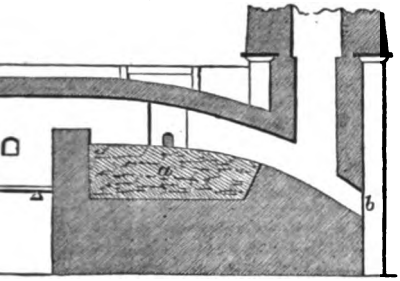
connected to one end, so that the jaws are alternately brought, at a rate of some 60 strokes a minute, nearer to the corresponding anvil-faces where the puddle-balls are placed to receive the pressure.

The puddle-ball, after having been hammered or squeezed, which occupies only a few seconds for each, is termed a *bloom* (*Luppe; loupe*), and is then drawn out into a bar by being rapidly passed several times, and while still red-hot, between grooved rollers, constituting what is termed a *forge-train* (*Streck-walzwerk, train de laminoir*), *fig.* 584. This consists of two pairs of rollers, R F, fitted in frames and driven

Fig. 584.

by machinery. In one pair of rollers, called the *roughing rolls* (*Cannelur-Walzen; cylindres dégrossisseurs*), there are corresponding V-shaped grooves round the surface. In the other pair of rollers, termed the *finishing rolls* (*cylindres finisseurs*), the grooves are flat, and in both they gradually decrease in size from one end of the rollers to the other, so that by passing the blooms successively through several pairs of grooves, they are reduced to bars of from 7 to 3 inches wide by from 1½ to ½ an inch thick. In this condition the iron is termed "puddle bar," or No. 1 iron.



After leaving the rolls, these bars, while still hot, are cut into short lengths by shears and the pieces tied together by strong wire in a bundle is termed a *pile* (*Paket; trousse*), which is brought to a welding heat in a reverberatory furnace called the "re-heating or mill furnace" (*Schweiss-ofen; four de chaufferie*), constructed somewhat like a puddling furnace, as shown by *fig.* 585. The hearth *a* of this furnace, on which the iron is placed, is made of sand, and slopes down towards the flue, so that any slag that is formed may run down and escape at the hole *b*, leaving the hearth quite dry.

The piles are raised as rapidly as possible to a full welding heat in the mill furnace,

Digitized by Google

then removed with tongs to mill-rolls, of a similar kind to those already de- but more highly finished, and drawn into bars which are again cut up, piled,

Fig. 585.

and then submitted to the same operations of heating and rolling several times, according to the required quality of the iron. Sometimes, after the first rolling of the iron into puddle bars, hammering is substituted in the place of drawing out between rollers. It is in this series of operations that the iron acquires its texture, and that close, uniform, and continuous fibre, upon which its strength and general good quality is considered to be chiefly dependent. The mode in which the pieces of iron are

l in the piles is considered to be of great importance as regards the result ; but notwithstanding the strong opinions expressed on this subject, little is s to the rationale of the connection apparently existing between the quality of and the mode in which it is wrought.

tain proportion of slag is produced during the reheating of the piles in the mill- which has a composition very similar to that of the slag from the puddling but the silica it contains is derived mainly from the sand forming the hearth.

all these successive operations have been completed, the iron is in the condition s "merchant iron," and the different degrees of quality are indicated as No. 2, c., or as "common," "best" and "best best," as well as by particular brands. es the waste of iron resulting from the formation of slag in refining, puddling, re is always a further waste due to the oxidation of the iron during the shin- ammering and rolling to which it is subjected. The product of this oxidation chiefly of magnetic oxide, which forms a crust on the surface of the hot iron, s off in scales, constituting what is known as "hammer-scale" or *mill-scale erschlag; battitures de fer*).

otal waste of iron in the conversion of pig iron into malleable iron, varies ac- to the kind of pig iron operated upon, and the amount of impurities in it, as upon the skill of the workmen. In South Staffordshire, the waste amounts to to 22 per cent. on the pig iron. In South Wales it sometimes amounts to to 28·5 per cent., though it is sometimes less than 13 per cent. Formerly the mounted in some cases to from 34 to 35 per cent. (Truran, *op. cit.* p. 215). The ction of iron bottoms for puddling furnaces, in place of sand, has contributed to reduce the waste of iron due to the formation of slag, and the use of ls containing ferrous or ferric oxides, as admixtures in the puddling or boiling n, in all probability tends to compensate the waste that would result from

Digitized by Google

atmospheric oxidation, inasmuch as the oxidation effected by these admixtures would be accompanied by an equivalent elimination of metal from them.

The greater part of this waste of iron takes place in the refining, amounting on the average to about 10 per cent. on the pig iron. In puddling refined metal, the waste is not more than from 4 to 7 per cent. In the mill-furnace the waste is much less, varying, according to the number of reheatings, and the size to which the iron is rolled, from 3·5 to 10 per cent. The consumption of iron in any stage of the manufacture, requisite to produce a ton of iron in a subsequent stage, is technically called the "yield," by a somewhat singular inversion of the meaning of the term.

The consumption of fuel in the various stages of the conversion of pig iron into malleable iron, varies according to the skill of the workmen, as well as the kind of fuel and iron used. In refining, from 6½ to 8 cwt. of coke per ton of metal made, is used when the pig iron has to be melted, and from 4 to 5 cwt. when the melted metal is run in from the blast furnace direct.

In "pig-boiling," the consumption of coal varies from 18 to 22 cwt. per ton of bar iron made, according as the coal is more or less bituminous and capable of burning with flame.

In puddling refined metal, the consumption is about 10 to 14 cwt. of bituminous coal, and from 17 to 18 cwt. of anthracitic coal per ton of iron made.

In heating the piles, the consumption of fuel is from 7 cwt. to 13 cwt. per ton of merchant bars, according as they are larger or smaller.

In connection with the consumption of fuel in the conversion of pig iron into malleable iron, it will be interesting to consider what amount of the heat, capable of being generated by the coal consumed, is really effective; how much of it is really used in heating the iron.

The temperature to which the iron requires to be heated in the puddling furnace may be taken as expressed by 1650° C.; and, assuming that the specific heat of cast iron increases above 350° C. in the same ratio that it does up to that temperature, it would, in that case, be about 0·26 at 1650° C.; accordingly, the quantity of heat requisite to raise iron from 15° C. to that temperature would be:

heat units.
$$424{\cdot}84 = 1650 - 15 \times 0{\cdot}26.$$

A further quantity of heat would be consumed in melting the iron, and though the latent heat of iron has not been determined, it may be assumed as equal to 30 heat units. Thus the total heat requisite to heat cast iron up to 1650° C. and to melt it would be:

heat units.
$$454{\cdot}84 = 424{\cdot}84 + 30.$$

and the quantity of heat requisite for one ton of iron would be:

heat units.
$$1{,}018{,}841{\cdot}6 = 2240 \times 454{\cdot}84.$$

Taking the average calorific power of coal, expressed in heat units, to be 7,778, it appears from the foregoing calculation, that the quantity of heat actually communicated to the iron amounts to less than that capable of being generated by 131 pounds of coal. Thus:

Coal, lbs.		Calorific power, heat units.		Quantity of heat generated, heat units.	Quantity of heat required to heat 1 ton of iron from 15° to 1650°C. and to melt it, heat units.
131	×	7,778	=	1,018,918	1,018,841·6.

Then, taking the quantity of coal consumed in puddling as being equal in weight to the pig iron worked, it appears that only 133 pounds out of every ton of coal burnt in the puddling furnace is really effective in heating the iron, or not more than one-sixteenth part. But though the quantity of heat actually communicated to the iron bears only this small proportion to the whole quantity generated by the combustion of the fuel used, it must be remembered that, under existing circumstances, this large consumption of fuel is unavoidable, since it is indispensable that, during the whole of the operation, the temperature should be maintained sufficiently high to keep the iron melted. For this purpose the rate of combustion must be high, and the intensely heated products of combustion must pass rapidly through the working chamber of the furnace. It has been estimated that in the ordinary puddling furnace, when the consumption of coal is at the rate of 240 pounds per hour, the volume of heated gas passing through the working chamber amounts to upwards of 72 cubic feet per second, or sufficient to fill the working chamber twice in a second, and that this is necessary in order to counteract the influence of conduction and radiation in reducing the temperature. (See Prideaux, *Elementary treatise on Fuel, particularly with reference to Reverberatory Furnaces.*)

Digitized by Google

nsequence of the extremely high temperature required to be maintained in d mill furnaces, that only so small a fraction of the heat generated by com- he fuel consumed, is really effective in heating the iron (Fuel, ii. 729), it is only the heat corresponding to the difference existing at any moment temperature of the iron, and the higher temperature of the atmosphere in chamber of the furnace, that is available for maintaining or raising the tem- the iron. So long therefore as the temperature of iron in a puddling furnace e 1650° C., the gas passing into the chimney must be at a temperature not at, and the whole of the heat corresponding to the quantity of gas discharged erature into the chimney, will be without any other useful effect. A variety ents have been contrived for turning this waste heat to account in raising riving the machinery of iron works; and by far the most simple and con- consists in doing away with the separate chimney to each furnace, and the heated gas escaping from the working chamber of several puddling o a spacious underground culvert, extending some distance away from the d communicating with flues passing through and round a large Cornish which the gas passes, and, after communicating its heat to the water, is ged into a lofty chimney capable of producing a draught sufficient for all connected with it.

umber of attempts have been made to introduce other improvements in of producing malleable iron by puddling; such, for instance, as the use of hot air, or of steam, or a mixed blast of air and steam, rotary puddling ., but excepting the admixture with the pig iron of materials containing oxides, and the use of iron hearth-bottoms in the puddling furnace, none of ts appear to have either any such scientific basis as to appear promising, een attended with sufficient success to demand consideration.

is different as regards the application of gaseous fuel in the refinery, rnace, and mill furnace. The gas used for this purpose is either the com- evolved from the throat of the blast furnaces in which pig iron is made, or pecially from small coal and other inferior kinds of fuel, by burning them in ner that the carbonic acid generated by the combustion of one portion, is s through a mass of incandescent fuel, so as to be converted into carbonic , together with the hydrocarbon vapours driven off from the fuel, passes ace to be heated, and is there burnt, much in the same manner as coal gas Bunsen's burner (See Bischof: *Die indirecte aber höchste Nutzung der rohen ialen*, 1848; also Scheerer, *Metallurgie*, i. 339). This method of using g been practised in Germany, and is now being introduced at some of the n this country, where it is to be hoped it will eventually not only admit of sed in iron working, without those disadvantages arising from the presence nd other impurities, when it is in contact with the metal; but that it may ome an important means of economising fuel, and especially of turning to t the vast quantities of small coal that have hitherto been almost entirely r descriptions of gas generators, and gas refining, puddling, &c., see the e quoted, and Percy, *Metallurgy*, ii. 596, 674, 716; *Ure's Dictionary of factures, &c.* ii. 573.

pheric process.—Under this designation, an entirely new method of alleable iron from pig iron, has been proposed within the last few years as for the operation of puddling. It consists in submitting melted pig iron of a current of air forced through it until it is sufficiently decarburised. nerated during this process, by the combustion of the carbon and silicon, and of the iron, is sufficient to heat the metal above the melting point of on, so that, when the operation is ended, the decarburised iron is obtained condition, and may be run into ingots, which are afterwards to be forged into ssemer, specifications, 1855, Nos. 2321, 2768; 1856, Nos. 356, 630.)

principle of this method is to effect the conversion of pig iron into on, wholly by the direct influence of atmospheric oxygen, and independently ction between the pig iron and the ferruginous or manganese oxides, or ntaining them, which takes place in the operation of puddling or boiling, according to all experience, and to such scientific data as there are for opinion, is so important a condition of the separation of sulphur and phos- pig iron. The result of the trial of this new method of producing on affords a still further confirmation of the important influence of the erred to as taking place in puddling. By the new method pig iron may be burised, and the silicon it contains may be entirely eliminated with ease; se is very different as regards the sulphur and phosphorus: for these which are so detrimental to malleable iron, far from being separated from subjected to this new mode of treatment, are either wholly unacted upon,

Digitized by Google

or so little affected, that, relatively, they are augmented, the amount of phosphor the decarburised iron obtained by this method, being greater than it was in th iron operated upon, while the amount of sulphur is but little reduced, as will be see the following analyses:

	Pig iron, per cent.	Bessemer iron, per cen
Analyst .	Tookey.	
Carbon	3·309	0·218
Silicon	0·595	
Sulphur	0·485	0·402
Phosphorus	1·012	1·102

At the present time no means of obviating this defect are known; consequently application of this method is confined to the working of such kinds of pig iron a practically free from sulphur and phosphorus; and hence, as regards the greater of the malleable iron manufactured in this country, there is no possibility o adoption of this method, although it admits of the decarburation of pig iron with greater ease, and much more rapidly than the operation of puddling. In Swede the contrary, where the pig iron produced is far less contaminated with sulphur phosphorus than most of that made in this country, the new method is being wo with great advantage. In England, it is also being applied in working some o better and more costly kinds of pig iron, but chiefly for the purpose of produc kind of steel which bears a higher price than ordinary malleable iron. For this re the further consideration of this method will be included in the article on STEEL.

5. **Iron smelting.**—In the extraction of iron from such of its ores as are suitab metallurgic purposes, and as it is now chiefly practised in iron-producing countries metal is always obtained in the carburetted state, commonly known as cast iron iron, or crude iron. The processes comprised in the smelting of iron are:—

1. The separation of water, carbonic acid, sulphur, and other volatilisable substa from the ore by the action of heat.

2. The reduction of the iron from the state of oxide, as it exists in the ore, t metallic state, by the action of carbonic oxide.

3. The separation of the earthy substances, commonly present in iron ores, from reduced metal, in consequence of the formation, at a high temperature, of fu compounds of those substances; and

4. The carburation and melting of the reduced metal.

In smelting the richer kinds of iron ore, *calcination* or *roasting* (*Röst grillage*) is not always requisite for the removal of volatilisable substances; but the majority of the iron ores used in that operation, it is very desirable that should undergo this preparatory treatment, as will be seen by reference to the ana of iron ores; and in all cases calcination is advantageous, inasmuch as it has the e of rendering the ore more porous, and consequently more susceptible of being duced.

The calcination of iron ores is effected by heating them to dull redness in co with air, either in heaps, with layers of coal at the bottom and alternating with l of the ore; or in kilns built of brick or masonry, from which the roasted ore ca drawn out at the bottom. The careful regulation of the heat applied is the important requisite in the calcination of iron ores, and it should be only just suffi to expel the volatilisable substances, without effecting, in the case of carbonaceous the reduction of iron to the metallic state, or, in the case of siliceous ores, the forma of ferrous silicate and fusion of any portion of the ore, so as to render it compact.

The changes effected by calcination consist chiefly in the separation of water, bonic acid, and bituminous substance when the ores are carbonaceous. In this case t may be a partial deoxidation of the ore, attended with formation of ferrous or magn oxide; but more generally the calcination of iron ores has the effect of producing f oxide to a greater or less extent, if the iron is not already in that state.

The sulphur in iron ores, generally present in the state of pyrites, is also to a g extent separated from them by calcination, in consequence of the decomposition of pyrites; one half of the sulphur being volatilised, while the residual iron sulphi converted by oxidation into sulphate, which may be decomposed if the heat is s ciently great The entire separation of sulphur from iron ores in this way is sel practicable.

An alteration of some kinds of iron ore similar to that resulting from calcina especially as regards separation of sulphur, is effected by exposing them for a tim the atmosphere. In this process of *weathering* (*Verwitterung*), pyritic minerals

there is a channel, called the *tapping hole* (*Stichloch; trou de coulée*) co with the hearth, to admit of the melted metal collected at the bottom o being run out at intervals. This channel is stopped up with clay or the metal and slag are accumulating in the hearth. That side of th wards which the hearth is prolonged, is called the *front* (*Arbeitsseite térieure*), while the opposite side is called the *back* (*Rückseite; partie* At this side there is an arched opening, *a*, called the *tuyere hole* there is generally a similar opening at each of the other sides. Oppo these openings an arch is turned in the outer brickwork of the furnace access to the tuyere holes. The upper extremity of the shaft is calle (*Gicht; gueulard*), and is generally surmounted by a low wall or chimne *tunnel head*, with openings at the side for introducing the materials into t

Air is supplied to the furnace through a series of pipes connected wi engine, each pipe terminating with a conical tube called a *tuyere* (*Du* surrounded with a hollow conical sheath, through which passes a stream prevent the melting of the tuyeres, extending through each of the tuyere h the interior surface of the hearth.

In the working of a blast furnace, the shaft is kept nearly filled wi materials used; these are introduced at intervals into the upper end, a sink down as the smelting progresses. Meanwhile a continuous supply of into the lower end of the furnace through the tuyeres, under a pressure 2 lbs. per square inch in charcoal furnaces; and from 2 to 5 lbs. per sq furnaces worked with coal or coke, and in quantity proportionate to th furnace and its rate of working, so as to maintain a rapid combustion o that part of the furnace immediately above the level of the tuyeres. (S *op. cit.*, p. 115.)

The reduction of the ferruginous oxides in the ore is effected by the rea place at a high temperature between these oxides and carbonic oxide, the combination of carbonic acid, resulting from combustion of the fuel, w quantity of carbon equal to that it contains; and, since ferric oxide contains of oxygen, the carbon and air requisite in these reactions for the reductio tity of ferric oxide containing 1 pt. of iron will amount to:

Iron.		Ferric oxide.		Parts by weight of carbon requisite in the state of carbonic oxide.		Parts by weight of oxygen requisite to form carbonic acid with half the carbon.	
1	=	1·429	=	0·3214	=	0·4285	=

or somewhat about 8 cwt. of coal, containing 80 per cent carbon, and 1 29 lbs. of air, or 54,443 cubic feet, per ton of iron made.

The reduction of the ferruginous oxide in the ore is not alone sufficient duction of the metal in an available condition: for it is but seldom that not contain a considerable admixture of earthy substances which require rated. They generally consist chiefly of silica, clay, or carbonate of lim seen by reference to the tabulated analyses of iron ores. These subst intimately mixed with the ferruginous oxide, and consequently with the re it is necessary that they should be melted as well as the metal itself, in they may separate according to their different densities in the liquid state of these substances alone is infusible at the temperature commonly produ smelting, and they can be separated only by being converted into sufficie compounds. The double silicates containing two or more bases, are subst fusibility corresponds to the requirements of this case, and it is by the such a vitreous silicate, termed *slag* (*Schlacke; laitier*), capable of be melted, that the separation of the earthy admixtures in iron ores is effecte

It is but rarely that these admixtures are of such a nature, and pres relative proportions, as to produce, under the influence of heat, a silicate be suitable for the purposes of iron smelting. Hence it is necessary to m ore some substance that will effect this result. The nature and propor *flux* (*Zuschlag; castine*) will of course depend upon the composition of t smelted, and must be regulated in accordance with the general principles the production of slags. (See METALLURGY.)

In smelting iron ores in which the earthy admixture is chiefly calcare some siliceous material, such as forge cinder or the roasted slag from pu naces, is added as a flux, or the ore may be mixed, in suitable proportion containing silica or clay. In the more frequent case of ores containing cl in some form, the material used as a flux is limestone or quicklime, in ord the formation of a double silicate containing alumina and lime as its basic c

existing between the silica and the bases, as well as that between the two The most fusible of them are those in which the oxygen of both bases amounts thirds of that in the silica, and the oxygen of the lime equals that in the

melting iron ores with charcoal, the temperature of the furnace is generally han when they are smelted with coke or coal, and on that account the slag to be more fusible than in the latter case. In smelting iron ores with coke especially when hot blast is used, the temperature is so much higher than in s worked with charcoal—not only where fusion takes place, but also at the art of the furnace—that the slag requires to be rendered less fusible by increas- proportion of lime to such an extent, in relation to the silica and alumina in that fusion may not take place before the reduction of the ore has been com- effected, and that the fragments of the charge may not become agglutinated, ain loose and porous while passing through that portion of the shaft where on takes place, and consequently more capable of being permeated by the g gas.

e smelting of siliceous ores there is a further necessity for the addition of lime, ore important than that connected with the production of a suitably fusible This arises from the circumstance that the double silicate, containing alumina rous oxide as its basic constituents, is very fusible, and from the consequent y to the formation of this compound, the result of which would be that a con- e amount of the iron would escape reduction to the metallic state, and pass off lag, thus giving rise to considerable loss of iron, besides other serious incon- es. This combination of ferrous oxide with the aluminous silicate in the ore t take place in the presence of a sufficient amount of lime, and in order to it as much as possible, the quantity of lime added to the ore is generally to form a slag in which the oxygen of the bases is equal to that in the silica.

nsequence of this difference, and the greater proportion of alumina in the ores Cleveland district, the slags produced in smelting them are much more stony s vitreous than those produced in smelting other ores. An increased addition would not remove this difference, which is due to the deficiency of silica in ion to the alumina present, and is probably accompanied by a less degree of ty of the slags. This circumstance will perhaps serve to account for the appa- cessity of a very high temperature in the smelting of these ores, and for the of the attempts that have been made to smelt them with cold blast. (I. L. Bell, p. 96.)

The preceding analyses of slags from furnaces in which the Cleveland ores are worked, will illustrate the difference between them and the slags produced in other districts.

The precise mode in which the carburation of iron takes place in the blast furnace is not known. From the fact that iron becomes carburated when heated in contact with hydrocarbon gases, or even with carbonic oxide, and since these conditions obtain in the blast furnace, it is highly probable that carburation may take place before the reduced iron reaches that part where there is a temperature high enough for fusion.

The state in which the carbon exists in the iron obtained from the blast furnace appears to depend very materially upon the temperature at which fusion takes place. The lower the temperature, the greater is the proportion of the carbon combined with the iron, and any circumstance which tends to induce fusion at a low temperature is almost invariably attended with the production of white iron. This is the case when charcoal is used as fuel, when the ore is readily fusible, and also when it is highly refractory and has not a suitable admixture of flux to determine fusion. When a furnace is worked with a large amount of ore in proportion to the fuel, or, as it is termed, with a "heavy burden," and when sulphur is present to any large extent, there is from the same reason a tendency to the production of white iron.

The production of grey iron containing carbon in the graphitic condition appears to require a temperature far beyond that of mere fusion, and it is probable, on that account, the introduction of carbon in this form may be due to action more of a physical than chemical nature, and consist in solution of the carbon by the melted metal rather than actual combination. When sulphur is present in any of the materials used in smelting iron, it is necessary to employ a very high temperature in order to obtain grey iron, because the melting point of iron is considerably lower when it contains sulphur.

Besides the reduction of the ferruginous oxide in the ore and the separation of its earthy constituents by the formation of a suitable silicate, it is necessary to maintain a very high temperature at the lower part of the furnace for the fusion of these products. This is effected by the rapid combustion of fuel under the influence of a blast of air forced in through the tuyeres.

The kind of fuel employed in smelting iron ores has a great influence both on the quality of the iron produced and on the mode of working. With bulky porous fuel, such as charcoal, combustion takes place more readily than with the more compact and denser kinds of mineral fuel, and from the greater liability of charcoal to crumble under pressure, the furnaces in which it is used are generally much smaller than those worked with coal or coke. But the main difference between these two kinds of fuel, as regards the smelting of iron, consists in the relative freedom of charcoal from earthy substances, and its entire freedom from sulphur and phosphorus, which are so prejudicial to the quality of iron. Hence the greater purity of the iron smelted with charcoal, provided the ore used be free from deleterious admixtures.

The consumption of fuel requisite in smelting iron for the production of a sufficiently high temperature of fusion, far exceeds the amount requisite for the reduction and carburation of the metal, which, as already pointed out, is less than half the weight of the iron produced, whereas that consumed for melting may amount to from one to two or three tons per ton of pig iron made.

The consumption of fuel in iron smelting is one of the most important points with regard to the economical production of the metal, and it is exceedingly desirable to reduce it to the lowest possible limit. The amount of fuel consumed per ton of pig iron made varies considerably, not only according to the kind of fuel, its calorific power, combustibility, texture, etc., but also according to numerous other circumstances. Among these the shape of the furnace has an influence, in so far as it admits of the easy and uniform descent of the charge in the shaft, and less fuel is consumed in making white iron than in making grey or foundry iron; but probably the most important difference in the consumption of fuel is that resulting from the use of air at the ordinary atmospheric temperature, or air previously heated to a temperature considerably higher.

In charcoal furnaces, the consumption per ton of pig iron made, is from half a ton to two tons and upwards, according as hot or cold blast is used. In smelting with coal or coke, the consumption is from two to three tons and upwards with cold blast, and from 23 cwt. to two tons with hot blast.

The fuel is introduced into the furnace at intervals alternately with the mixture of ore and flux, and in uniform proportions, termed the *charge* (*Beschickung; lit de fusion*), and the relative proportion of fuel or of ore is termed in either case the "yield;" sometimes also in the case of the ore it is termed the "burden."

The total weight of the charge per ton of pig iron made, will vary, according to the kind of ore, flux, and fuel used, from four to five or seven tons and upwards, when the materials are used in the raw state; but by far the greater quantity of the material supplied to a blast furnace in smelting iron, consists of the air by which combustion is

Digitized by Google

orted: for taking carbonic oxide to be the ultimate though not the immediate uct of the combustion, the quantity of air required would amount to at least five s the weight of the fuel burnt, taking the combustible portion of the fuel to be l to 85 per cent. of carbon, and allowing for the carbon consumed in carburating ron. Consequently the total quantity of air supplied to blast furnaces will be as ws, according to the consumption of fuel given above:

	tons. cwt.	tons.	tons.	
uel consumed . . .	23	2	3	per ton of iron made.
uantity of air . . .	5 15	10	15	
ubic feet at 60°F. . .	168,038	292,240	438,360	

ne greater part of this air is consumed in burning that portion of the fuel isively concerned in the production of a temperature high enough for effecting n; and that part which is consumed in the combustion of the fuel requisite for eduction of the ore, does not amount to quite twice the weight of the iron made.

ne temperature of the gaseous products of combustion discharged from blast aces differs according to the kind of materials used and their condition, the height ne shaft, and the mode of working. In the case of charcoal furnaces, the gas has rally a temperature of from 300° to 400° C., while that from furnaces worked with or coal, is from 550° to 1000° C., according to circumstances. The whole of the corresponding to the temperature of the gas discharged is waste heat, and ough it has served, at an earlier stage of the process, to produce the high temperature ssary for fusion of the metal and slag, it is still available for any purpose to which n be applied.

ne great extent to which the heat generated in the smelting of iron ores is thus pated, without producing the full useful effect of which it is capable, may be ed of from the fact that the weight of the gas discharged from a blast furnace is than equal to the entire quantity of both air and fuel consumed, or from 17 tons per ton of pig iron made.

ut besides the waste of heat due to the high temperature of the gas discharged, there further and more considerable loss of heat, due to the fact that it contains a large unt of carbonic oxide, together with some hydrocarbons and hydrogen, and is in all nary cases sufficiently combustible at the temperature at which it is discharged, to fire on coming in contact with atmospheric air at the top of the furnace. This e is proportionate to the extent to which carbonic oxide is produced. Taking the age consumption of fuel in iron smelting to be represented by a quantity of carbon l to twice the weight of the pig iron produced, if that portion only which is isite for the reduction of ferric oxide be ultimately discharged from the furnace in state of carbonic acid, the quantity of fuel fully utilised in producing the entire ing effect of which it is capable, will be only about one-sixth part of the whole.

	Quantity of heat generated by perfect combustion of carbon. parts by weight

hen, since the calorific power of carbon burnt to carbonic oxide is only about one- d of its calorific power when burnt to carbonic acid, or as

2473 : 8080 = 1 : 3·223,

heating effect produced by the remaining five-sixths of the fuel consumed, so as regards its ultimate condition when discharged from the furnace, will be less one-third the effect it is capable of producing:

antity of heat able of being erated by com- on of 1·6786 car- o carbonic acid. heat units.		Quantity of heat generated by com- bustion of 1·6786 car- bon to carbonic oxide. heat units.					Difference.
13564	—	4151·1778	=	1·6786	×	2473	= 9413

difference representing the heating effect capable of being produced by the carbonic le, and amounting to no less than 58·25 per cent. of the whole heating effect able of being produced by the fuel consumed.

o far, therefore, as regards the condition in which the products of combustion are harged from a blast furnace, the only portion of the fuel consumed so as not to be her available as a source of heat, is that equivalent to the reduction of the iron in ore, and, supposing the metal to be contained in the ore in the state of ferric le, it would be only about one-third the weight of the iron made, or 16 per cent.

Digitized by Google

of the fuel consumed. The greater part of the heat corresponding to the r
84 per cent. of fuel consumed, leaves the furnace in some form or other in th
sensible heat, or as heat capable of being generated by combustion, and is still
for heating purposes.

But, notwithstanding this large difference between the amount of fuel full
and that which still remains available as a source of heat, after its combusti
blast furnace, it must not be supposed that the large amount of fuel consume
smelting, as compared with the amount which is fully utilised, does not, in
furnace, exercise its full heating power. For though only a small portion of t
heat generated is rendered latent by the fusion of the metal, &c., the whol
required for producing the temperature at which those changes take place;
which passes off in the gas does not indicate a useless consumption of fuel, and
be regarded as waste heat, in so far as it is allowed to escape without being
such further advantage as it is still capable of.

In the immediate neighbourhood of the tuyeres, the fuel is burnt, under
ence of the blast, to carbonic acid, generating the full amount of heat corre
to its calorific power, and producing there the greatest increase of tempera
capable of producing when burnt with atmospheric air. (See Fuel, ii. 726.)

It is at this part of the furnace that, while the fuel is being consumed, th
metal and the earthy substances mixed with it are rapidly melted, and, fall
into the hearth, make room for a fresh quantity of the materials in the shaft of th
to sink down and undergo the same change, while the gaseous products as
communicate their heat to the materials in the higher part of the shaft.

When the iron ore smelted contains carbonic acid or water, and has
previously calcined, those substances will be separated during the descent of t
in the shaft, and will mix with the products of combustion. This will also b
with the carbonic acid of the limestone used as a flux, and if coal be used a
volatilisable portion will likewise be expelled, and mix with the ascending gas.

In proportion as the extent of this admixture is greater, the gas will hav
heating power when burnt, and therefore it is desirable to reduce the amou
bonic acid and water-vapour in the blast furnace gas, by previous calcinati
ore and limestone, whenever the gas is to be used as fuel.

As a consequence of the different physical conditions of the products resul
the changes that take place in smelting iron ores, those products are continu
charged from the blast furnace in a manner exactly the reverse of that in
raw materials are supplied to it; the melted iron and slag flowing out at th
while gas escapes from the top or throat of the furnace.

In considering more minutely the conditions under which these products ar
and the chemical nature of the changes from which they result, it will be c
to follow the course of the air supplied to the furnace as it passes from the
the top.

The direct and perfect combustion of the fuel is, in all cases, confined with
paratively small portion of the furnace, and in furnaces worked with charcoal, i
only to a short distance above the level of the tuyeres. Beyond that porti
furnace, heat is communicated to the materials in the upper part of the furna
ascending heated gaseous products of combustion, consisting of a mixture of
and carbonic acid, the temperature of the gas being proportionally reduce
as it passes up to the mouth of the furnace. But since the materials in th
the furnace immediately above the region of combustion are at a high red
carbonic acid enters into combination with a further quantity of carbon, an
verted perhaps entirely into carbonic oxide, its volume being thereby doubl
reaction being attended with a considerable absorption of heat (see Fuel, ii.
temperature of that part of the furnace where it takes place, though still
must be, on that account, much lower than it is within the region of direct co
near the tuyeres.

The following analyses of gas, taken from different heights in the shaft
furnaces, will serve in some degree to illustrate the nature of the changes resul
the reaction taking place between the solid and gaseous materials contain
furnace, and *figs.* 587 and 588 represent the shape of two of the furnaces fr
the gases were taken.

The formation of carbonic oxide is probably one of the most important f
this process: for there is every reason to consider that the reduction of the
as it descends towards the boshes of the furnace, is effected mainly, if not en
this gas, aided perhaps in some cases, by hydrocarbon vapour or gas produ
the fuel by the action of heat. Previously to this, no alteration of the rel
portion existing by weight or volume, between nitrogen and oxygen in at
air, would be effected either by the combustion of the fuel or by the s

production of carbonic oxide. But by the reduction of the ore resulting from the reaction of carbonic oxide with ferrous or ferric oxides at a high temperature, carbonic acid is again produced, equal in volume to the carbonic oxide undergoing the change, and the effect of this transfer of oxygen from the solid to the gaseous contents of the furnace would be to produce a proportionate alteration of the ratios existing between both the relative weights and volumes of the nitrogen and oxygen. However, the influence exercised by this change on the composition of the gas passing upwards through the furnace will be slight; for, since the consumption of fuel in smelting iron ores so far exceeds the amount that would be chemically sufficient for the mere reduction of the ferric oxide, and since it is probable that the whole of the carbon consumed passes into the state of carbonic oxide at some part of the furnace not far above the level of the tuyeres, it follows that the extent to which carbonic acid is produced by the reaction between ferric oxide and carbonic oxide, must be small compared with the total amount of carbonic oxide produced in the operation; and, in fact, taking the consumption of fuel to be at the rate of 2 pounds carbon to 1 pound of pig iron made, only one-sixth part of the carbonic oxide formed at the lower part of the furnace, would be converted into carbonic acid by the reduction of the iron in the ore from the state of ferric oxide, taking place at the upper part of the furnace.

Fig. 587.

Norwegian charcoal blast furnace.

Fig. 588.

English blast furnace. Alfreton, Derbyshire.

Most probably the reduction of ferric oxide by carbonic oxide takes place progressively, and since the temperature requisite does not exceed that of dull ignition, it may extend over a considerable range in the descending column of materials, in proportion to the temperature prevailing in the upper part of the furnace.

From the relation existing between the calorific power of iron and that of carbonic oxide (see HEAT, p. 105), it is probable that the reduction of ferric oxide by carbonic oxide, generates a certain amount of heat, since the quantity of heat generated by the combustion of iron is less than that generated by the combustion of the carbonic oxide requisite for its reduction from the state of ferric oxide. Thus:

Quantity of heat generated by combustion of 0·75 lb. carbonic oxide, heat units.		Quantity of heat generated by combustion of 1 lb. iron to ferric oxide, heat units.		Difference.
1802·25	—	1582	=	220

Unless, therefore, the thermal effect of the combustion of carbonic oxide by the condensed oxygen in ferric oxide, be different from that of its combustion by gaseous oxygen, this change would be attended with an increase of temperature. But in any case it does not appear that there is any other cause operative in reducing the temperature at the upper part of the blast furnace, save the transfer of heat from the ascending gas to the colder materials supplied from time to time at the top, as the charge descends, and—if hydrated or carbonated ores, or limestone, or fuel containing volatilisable substance, be used—the absorption of heat accompanying the change of water into vapour and of carbonic acid into gas.

Consequently, the maintenance of a high temperature in the upper parts of the blast furnace must have the effect of preparing the materials constituting the charge, for passing rapidly through that stage of the process taking place near the level of the tuyeres, which, as regards the present system of working, consists probably in the mere fusion of the metal and slag, and the combustion of the remaining fuel. Accordingly, a reduction in the quantity of material in the charge would admit of a given temperature being maintained at the upper part of the furnace with a less consumption

alloys of iron may be prepared by fusing different metals with iron wire, in a blast furnace, a small quantity of ferric oxide being added to decarbonise the iron.

1. An alloy of iron and aluminium, nearly in the proportion Al^2Fe, is obtained by melting 10 pts. aluminium and 5 pts. ferrous chloride with 20 pts. of a mixture of the chlorides of potassium and sodium in equivalent proportions, and treating the resulting crystalline regulus with dilute hydrochloric acid. The alloy then remains in iron-coloured six-sided prisms; it is attacked by hydrochloric acid, and soda-ley extracts from it a small quantity of aluminium (Michel, Ann. Ch. Pharm. cxv. 104). See also ALUMINIUM (i. 155). The peculiar excellence of the Indian steel, known under the name of "wootz," has been ascribed to the presence of aluminium in it; but there is room for doubting whether this is the case (Faraday and Stodart, Quart. Journ. of Science, 1819–20, ix. 320; Karsten, *Eisenhüttenkunde*, i. 484). (See STEEL.)

2. With Antimony (i. 316).

3. With Arsenic. *Arsenical Iron, Arsenosiderite.*—Two compounds of arsenic and iron, Fe^4As^6 and $FeAs^2$, known by these names, occur as natural minerals. They appear to be isomorphous, forming trimetric crystals, in which $\infty P : \infty P = 111° 30'$ (Greg), 122° (G. Rose); cleavage rather distinct in one direction; also massive. Hardness = 5—5·5. Specific gravity, from 6·80 to 8·71. Lustre metallic. Colour between silver-white and steel-grey. Streak greyish black. Fracture uneven. Brittle. Heated in a glass tube, they yield a sublimate of metallic arsenic; on charcoal before the blowpipe, they give off arsenical fumes and leave magnetic globules. Nitric acid dissolves them with separation of arsenious acid.

Arsenical iron always contains sulphur, generally between 1 and 2 per cent.; a specimen from Geier, in the Erzgebirge, contains 6 per cent. If this be reckoned as arsenical pyrites (mispickel), $Fe^2As^2S^2$, the remainder is found to contain, in the lighter varieties (specific gravity 6·24—7·00), from 67·4 to 68·4 per cent. arsenic, and 32·6 to 31·6 iron, agreeing nearly with the formula Fe^4As^6, which requires 66·8 As and 33·2 Fe; and in the heavier varieties (specific gravity 6·80 to 8·71), from 71·35 to 73·49 arsenic, and 27·88 to 26·51 iron, agreeing nearly with the formula $FeAs^2$, which requires 72·84 As and 27·16 Fe. (*Rammelsberg's Mineralchemie*, p. 19.)

Arsenical iron occurs, associated with copper-nickel, at Schladming in Styria; with serpentine at Reichenstein in Silesia, and at Löling, near Hüttenberg, in Carinthia, in a bed of spathic iron ore, associated with bismuth and scorodite; at Geier in the Erzgebirge; in Bedford County, Pennsylvania, and in Randolph County, North Carolina, where a mass was found, weighing nearly two pounds. (Dana, ii. 61.)

Gehlen, by melting 54 pts. iron with 108 pts. arsenic in a closed vessel, obtained an arsenide of iron, having nearly the composition Fe^2As^2; it was white, brittle, and very easily pulverised. Arsenical cast iron (see *ante*, p. 335).

4. With Bismuth.—An alloy prepared by melting together 3 pts. bismuth and 1 pt. iron is still magnetic.

5. With Copper. (See ii. 42.)

6. With Gold.—1 pt. iron forms with $\frac{1}{4}$ pt. gold a silver-white alloy; with 1 pt. gold, a grey alloy.

7. With Lead.—The two metals unite with difficulty when fused together, forming two alloys, arranged one above the other, the lower containing but very little iron, and the upper but a very small quantity of lead (Morveau). By reducing a slag containing lead and iron in a crucible lined with charcoal, Biewend (J. pr. Chem. xxiii. 252) obtained a well-fused alloy, which was hard, almost perfectly brittle, lustrous, and magnetic; it had a light steel-grey colour, a fine-grained laminar fracture, and contained 96·76 per cent. of iron and 3·24 of lead.

8. With Manganese.—Cast iron, alloyed with manganese, becomes white and more brittle; when the proportion of manganese amounts to 22 per cent. the iron ceases to exhibit magnetic properties. (Mushet.)

9. With Mercury.—An amalgam of iron with mercury is described by Joule. (Brit. Ass. Reports, 1850, p. 55.) See MERCURY.

10. With Molybdenum.—Molybdide of iron is bluish-grey, hard, brittle, fine-grained, and magnetic; fusible before the blowpipe when formed of equal parts of the two metals, but not so when formed of 2 pts. molybdenum and 1 pt. iron.

Many samples of the so-called "bears" (*Eisen-sauen*) which are metallic masses found in the hearths of blast furnaces in which copper is smelted, as at Mansfield (ii. 31), likewise consist of iron alloyed chiefly with molybdenum; *a*. Bear from the upper works at Eisleben, obtained in the fusion of bituminous marl-slate in smelting furnaces. α. Fine-grained. β. Coarse-grained (Heine, J. pr. Chem. ix. 176).—*b*. The so-called Magdeburg meteoric iron, containing slag mixed with bronze-yellow copper-cinder; probably the bear from a copper furnace. α is the analysis of a fine-grained sample, β of a coarse-grained sample, by Stromeyer (Pogg Ann. xxviii. 551); γ is the analysis by Wehrle (Zeitschr. Phys. v. W. iii. 168).—*c*. Bear found in the neighbourhood of the

Digitized by Google

containing platinum, iron, carbon, and hydrogen, is boiled with nitric acid, a black residue is left. This latter substance, when heated to 200°, detonates slightly, producing a faint light, but if gradually heated, decomposes with detonation; it dissolves in nitromuriatic acid, yielding a solution containing a larger portion of platinum, with but little iron. (Faraday and Stodart. Phil. Trans. 1822, p. 257, and Quart. Journ. of Science, p. 329.)

Cast iron and platinum form a dark, malleable, very hard alloy.

14. With Potassium.—An alloy having nearly the composition Fe^4K^2, is obtained by igniting 12 pts. iron filings with 8 pts. pulverised tartar; it has the aspect of bar-iron, is very hard; can be forged and welded, but oxidises very rapidly in air and water. (Gay-Lussac and Thenard, *Recherches Physico-chimiques*, i. 238; Calvert, Phil. Mag. Oct. 1855.)

15. With Rhodium.—1 pt. rhodium and 1 pt. steel form an alloy having a specific gravity of 9·176, and a very fine colour and surface for metallic mirrors; it does not tarnish in the air. An alloy of 1 pt. rhodium and 50 to 100 steel is very hard, tolerably tough, requires for tempering a temperature higher by 39° than common steel, and by 17° than Indian steel. (Faraday and Stodart, *loc. cit.* p. 329.)

16. With Silver.—Iron is said to take up a small quantity of silver when melted with it.

17. With Tin.—When iron and tin are heated to redness together, there is formed: *a*. An alloy of 22 pts. tin and 1 iron, somewhat harder than tin, and magnetic; and below it *b*. A compound of 2 pts. iron and 1 pt. tin (nearly FeSn), which is white, very hard, slightly malleable, and difficult of fusion: this constitutes *tinned Iron-plate*.—In cast-iron retorts in which the tin-amalgam used for silvering mirrors is continually distilled, for the purpose of regaining the mercury, an alloy of tin and iron is formed, amounting to between 1 and 2 per cent. of the tin obtained: when the tin is poured out of the retorts, this alloy partly floats upon it in scales, and is partly deposited at the bottom in the form of a doughy mass. It may be freed from the pure tin which adheres to it, either by boiling with hydrochloric acid, which dissolves the latter, or by treating it with nitric acid, by which the free tin is oxidised while the alloy is not attacked. When thus purified, it has the form of shining square needles, of specific gravity 8·733, brittle, and fusing at an incipient white heat. The powder of this compound, when thrown into the flame of a candle, burns with emission of sparks and a white smoke. It does not rust in the air, when moistened with water. It is not attacked by nitric acid at any temperature or any degree of concentration; it dissolves slowly in boiling hydrochloric acid; but rapidly and completely, and with violent action, in nitromuriatic acid. (Lassaigne, *J. Chim. méd.* vi. 609.)

Deville and Caron (Compt. rend. xlvi. 920) obtained the alloy FeSn, in broad shining laminæ, which were but slightly attacked by hydrochloric acid.

An alloy containing FeSn remains in the preparation of stannous chloride from Banca tin (see Tin), in slender (probably quadratic) needles of specific gravity 7·44, fusible only at a white heat; it solidifies in the crystalline form on cooling, and is then magnetic. The crystals are nearly insoluble in hydrochloric and nitric acid, but dissolve easily in nitromuriatic acid; they burn in the flame of a candle. (Nöllner, Ann. Ch. Pharm. cxv. 233.)

It has been proposed to harden malleable iron rails by introducing a portion of tin into the metal, but it has been found to render the iron extremely brittle and "cold short," and also incapable of being welded. (Karsten, *Eisenhüttenkunde*, i. 508, and Percy, *Metallurgy*, ii. 161.)

18. With Titanium.—Pig-iron often contains titanium (p. 335), which appears to be derived chiefly from the clay of the ore, or from other siliceous compounds added as fluxes. In three samples of grey pig from the iron ore of Westbury in Wiltshire, Riley found 1·15, 0·71 and 0·47 per cent. titanium. The titanium is either minutely disseminated through the iron or else alloyed with it. The presence of titanium in the ore or in the flux appears to improve the quality of the iron, and render it of excellent quality both for castings and for conversion by the Bessemer process; but according to Riley's observations, the titanium does not appear to remain with the iron, at least only in very minute quantity, when it is converted into bar iron or steel. Mushet has patented the use of titanium in the manufacture of iron and steel, and the alloying of titanium with iron and steel; but samples of his steel, in the manufacture of which titaniferous ores were used, did not yield any appreciable evidence of titanium. (Riley, Chem. Soc. J. xvi. 387; see *ante*, p. 335.)

19. With Tungsten.—Iron and tungsten may be united by fusion. It is stated that steel of very superior quality may be made by simply melting cast steel, or even iron, either with metallic tungsten or with the so-called native alloy, prepared by

Digitized by Google

heating a mixture of powdered wolfram and fine carbonaceous matter in a lined with charcoal. (Bernouilli, Pogg. Ann. 1860, xxi. 573.)

ith Zinc.—Iron takes up zinc when heated with it. A brittle friable alloy y formed by melting zinc in vessels of wrought or cast iron, or by dropping melted zinc; sometimes crystalline compounds of ferruginous zinc are l. (Percy, *Metallurgy*, ii. 153.)

mersing malleable iron or cast iron, perfectly free from oxide on the surface, d zinc, the iron becomes covered with a coating of zinc, probably in conse- f the two metals being alloyed superficially. Iron thus coated with zinc is le to undergo oxidation when exposed to the atmosphere, and is largely l under the name of *galvanised iron*.

, BROMIDES OF. Iron unites with bromine in two proportions, form- *dibromide* or *ferrous bromide*, $FeBr^2$, and the *tribromide* or *ferric bromide*,

ous bromide is a yellowish substance obtained by passing bromine- ver gently ignited iron wire. It is soluble in water, and may be obtained ion by dissolving iron in hydrobromic acid, or in a mixture of bromine er. The solution yields by evaporation rhombic tabular crystals, contain- $r^2.6H^2O$. When exposed to the air it turns brown, and deposits *ferric ide*.

ic bromide, Fe^2Br^6, is produced by heating ferrous bromide with bromine, aporating to dryness a solution of iron in excess of bromine-water. It is a d mass which deliquesces in the air. It may be obtained in solution by g ferric oxide in hydrobromic acid, or by mixing the aqueous solution of the romide with bromine.

, CARBIDES OR CARBURETS OF. See Cast Iron (p. 329) and By heating alkaline ferrocyanides to redness, a compound of carbon and iron is , consisting of FeC^2.

other definite compounds of iron and carbon have been supposed to exist, viz. ^{3}, and Fe^4C, according to Karsten and Berthier (Ann. des Mines [3] iii. 229). cently Gurlt (Chem. Gaz. xiv. 230) has endeavoured to show that there is carbide, represented by the formula Fe^5C. The nearest approach to a definite d of carbon and iron is specular iron, which may perhaps consist essentially carburet; but the evidence of the existence of these compounds is exceedingly t.

, CARBONATE OF. See Carbonates, i. 784.

, CARBURETTED, ANALYSIS OF. It has already been mentioned iron contains, besides carbon, which is an essential constituent of it, a con- number of other elements, both metallic and non-metallic, that many of these are not completely removed in the processes to which the iron is subjected to t into bar iron and steel, and that all of them have more or less influence on the f the iron. It becomes, therefore, an important problem to detect these lements in iron, and, as far as possible, to estimate their amount.

on used for the analysis must be finely divided, as in the form of filings, or borings; very hard iron, such as specular iron, or hard steel, may be com- in a steel mortar, and sifted. The iron must of course be free from dust, rust, other foreign substances.

imation of the entire amount of Carbon.—To estimate the whole of the iron, both free and combined, the iron must be dissolved, without evolution gen, because that gas would carry some of the carbon with it; or the car- iron must be completely oxidised, and the carbon estimated as carbonic

carburetted iron is brought in contact with *chloride of silver*, *cupric chloride*, *chloride*, these compounds are reduced to metallic silver, cuprous chloride, and chloride respectively, while the metallic iron is also converted into ferrous which dissolves, and the whole of the carbon remains behind, together with nd various metals. The action of chloride of silver is very slow; the most con- eagent for this purpose is *cupric chloride*. A quantity of the iron (5 to 10 grms.) d with a moderately concentrated aqueous solution of cupric chloride, free from acid, whereupon metallic copper is precipitated, and ferrous chloride is formed. as trituration with a glass rod shows that the deposit is free from hard par- iron, the solution is decanted and the residue is drenched with a concentrated of cupric chloride acidulated with hydrochloric acid, in order to convert the copper into cuprous chloride, and dissolve it. The solution is then filtered a glass tube drawn out at the lower end to a narrow neck, and plugged with (or platinum-sponge), so as to retain all undissolved particles. Impure carbon

Digitized by Google

is thus obtained, the weight of which may be determined by weighing the tu at 124°–130° C., both before and after the experiment.

Ferric chloride may also be used instead of cupric chloride, the free acid c in the solution being previously neutralised with carbonate of sodium or carb calcium. The basic ferric salt deposited in the reaction may be removed b hydrochloric acid or solution of ferric chloride.

The iron may also be dissolved, without loss of carbon, by nitric acid, provi first drenched with water, and then nitric acid free from chlorine or nitrous aci As soon as the solution has attained a sufficient degree of concentration, it is po the residue is drenched with fresh quantities of water and aqueous acid, and th yellowish solution, which contains nitrate of ammonia and nitrate of iron, i clarify, and finally filtered as above.

Another method is to heat the finely divided iron in a stream of dry *chlorine* viously freed from air by passing through a red-hot tube containing finely divided

Bromine or *iodine* may also be used instead of chlorine, and in the w Morfitt and Booth (Chem. Gaz. 1853, p. 358) drench the iron (not ver divided) with a small quantity of water, add iodine (*5* grms. to 1 grm. iron), a it for five or six hours, till the action is finished; then pour off the liquid, ac water and iodine, if any iron still remains, and filter. Care must be taken no too much water, and not to allow the action to go on too long, otherwise a p the carbon will be lost. The charcoal which remains after the solution of i iron has been filtered off, is washed with hot water, then with hydrochloric a again with water, and the residue is weighed.

The carbon obtained by either of these methods is not pure, but is mixe small quantity of iron, and a larger quantity of silicic anhydride and oxide o The amount of pure carbon may be determined, either by the loss which the sustains when ignited in contact with the air, or by burning the carbon as in analysis, with oxide of copper, or better with chromate of lead, or with a mixtur salt and chlorate of potassium, or in a stream of oxygen, and weighing the c carbonic anhydride by absorption in caustic potash.

Deville (Compt. rend. li. 938) separates the pure carbon at once by igni finely divided iron in a current of dry hydrochloric acid gas, quite free fro spheric air. The iron and all the foreign constituents, except the carbon, converted into volatile chlorides, and pure carbon remains behind.

2. ***Estimation of the Graphite or mechanically mixed carbon.***—This is the which remains behind mixed with silica, and sometimes also with humus-like compounds, when the iron is dissolved by dilute acids. To estimate it, the iron is d out by dilute hydrochloric acid of specific gravity 1·1; the washed residue is in potash-ley of specific gravity 1·1, to remove silica and humus-compounds, th water, then with hot hydrochloric acid, and lastly, with hot water, after whi dried, weighed and ignited in contact with the air, the loss of weight whic sustains being reckoned as graphite (Morfitt and Booth). Buehner (J. p lxxii. 364) washes the residue with boiling water, potash-ley, alcohol, and fina ether; then dries, weighs, and ignites as above. Gurlt (Polyt. Centralbla p. 378) treats the finely divided iron with recently precipitated chloride of si solution of sal-ammoniac, digests the residue with cyanide of potassium to chloride of silver, with potash to remove silica and combined carbon, then wi acid to remove metallic silver: the residue consists of graphite, which is to b as above.

3. ***Estimation of the combined Carbon.***—The carbon actually in combinat the iron is for the most part converted, during the solution of the metal, into hydrocarbons, which escape with the hydrogen, and impart to it a well-know sive odour; part of this carbon, however, always remains in the liquid form to the graphite. When carburetted iron is digested with *chloride of silv* chloride, or cupric chloride, as already described, the whole of the carbon behind, and on treating the residue with potash-ley, that which was origina bined with the iron dissolves, and may be separated, together with silica, b saturation with hydrochloric acid, evaporation to dryness, and washing. The of carbon in the residue thus obtained may then be determined, either by th weight sustained on ignition, or by combustion with chromate of lead. The c carbon is, however, more generally estimated by difference.

4. *Estimation of Silicon.*—The amount of this element may be deter igniting the residue obtained in the preceding operation; the carbon the away, and silica remains behind; as, however, a small portion of the carbon escape combustion, and the residue likewise contains a certain portion of slag, silica must be dissolved out by potash-ley of specific gravity 1·1 (which will n the slag), and then precipitated by supersaturation with hydrochloric acid.

Digitized by Google

water containing 1 per cent. of nitric acid, and dried at 95°. 100 pts. of the dri precipitate correspond to 1 pt. phosphorus.

8. *Estimation of Arsenic.*—When arseniferous iron is dissolved in dilute hydr chloric or sulphuric acid, the arsenic is not given off as arsenetted hydrogen, but converted into arsenic acid (H. Rose), which remains dissolved if the solution h been made in the cold, but is precipitated from warm solutions not containing t great an excess of acid, as basic ferric arsenate, and is therefore often found in t carbonaceous residue.

When the iron is dissolved in nitric or nitromuriatic acid, the arsenic is convert into arsenic acid, and may be precipitated as basic ferric arsenate (together with pho phate) by boiling the solution with acetate of sodium, after the greater part of t ferric oxide has been reduced to ferrous oxide by heating it with sulphite of sodiu The precipitate is then decomposed by sulphide of ammonium, and the filtrate, acid lated, and treated with sulphydric acid, yields a precipitate of sulphide of arsen Or the iron may be dissolved in hydrochloric acid, with addition of a little nitric ac to dissolve all the arsenic; the filtrate heated with sulphite of sodium, to reduce the ferric to ferrous chloride; and the solution, freed from excess of sulphurous ac may be treated with sulphydric acid, with the usual precautions; the arsenic is th precipitated as trisulphide (together with the sulphides of copper and lead, if presen

As a portion of the arsenic sometimes remains in the carbonaceous residue, th residue must be examined, either by treating it with sulphide of ammonium, and pr cipitating the arsenic from the filtrate by sulphydric acid, or by fusing it with nitra and carbonate of sodium, and precipitating the arsenic as ammonio-magnesian arsena

The pulverised iron may also be fused with nitrate and carbonate of sodium, th silicic and sulphuric acids separated as above, and the arsenic then precipitated by su phydric acid, or if no phosphorus is present, by ammonia and sulphate of magnesiu

9. *Estimation of Manganese, Cobalt, Nickel, and Zinc.*—These metals may a be separated from iron, by precipitating the latter from a neutral solution in which the iron exists as ferric salt, with benzoate or succinate of ammonium, or from ac solution, with carbonate of barium.

10. *Estimation of Copper and Lead.*—The precipitate, thrown down as abo described by sulphydric acid from the reduced iron solution, sometimes contains trac of these two metals. The arsenic may be extracted from it by monosulphide of pota sium; and the residue, oxidised with nitric acid and treated with sulphuric acid, yiel insoluble sulphate of lead and a soluble copper salt.

11. *Estimation of Aluminium.*—For the method of separating this metal fro iron, see i. 155.

12. *Estimation of Magnesium, Calcium, and the Alkali-metals.*—The metals remain in solution after the iron has been precipitated as ferric oxide by be zoate or succinate of ammonium, or by carbonate of barium, and may be separated an estimated by the usual methods.

13. *Estimation of Chromium, Vanadium, Titanium, Molybdenum, an Tungsten.*—These metals occur especially in the black residue which remains wh pig iron is dissolved in dilute acids, and may be sought for either in this or directly the iron.

To detect and separate chromium and vanadium, a large quantity of the pulv rised iron is fused with 12 pts. nitrate and 1 pt. carbonate of sodium; the fused mas (which likewise contains silicic, phosphoric, and arsenic acids) is mixed with such quantity of nitric acid that it still retains a slight alkaline reaction, but does not giv off any nitrous acid (which would reduce the chromic and vanadic acids); the solutio is mixed with chloride of barium; the washed precipitate is treated with sulphur acid; the solution is saturated with ammonia and evaporated; and a lump of sal-amm niac is thrown in, whereby vanadate of ammonium is thrown down as a yellow white crystalline powder, while the chromate remains in solution. The vanadate ammonium, heated in contact with the air, yields dark red vanadic acid, the quantit of which can then be determined.

According to Sefström, the vanadic (and chromic) acid may be separated from th fused mass, after neutralisation with nitric acid, by the addition of a lead-salt; th washed precipitate is then boiled with strong alcohol and hydrochloric acid, the resultin blue solution of vanadic (and chromic) oxide, after being evaporated, is oxidise by nitric acid or chlorine-gas, then mixed with potash-ley, evaporated down, an fused; the fused mass is dissolved in water; and the vanadic acid is precipitated, as above, by sal-ammoniac. The liquid filtered therefrom (after separation of pho phoric and arsenic acids as ammonio-magnesian salts) yields with sulphydric acid precipitate of chromic hydrate, while sulphide of molybdenum remains in solution whence it may be precipitated by acids, and, when fused in a narrow tube, yields pur sulphide of molybdenum.

weighs it. The weight of the residue, consisting of graphite mixed with t anhydride, being thus determined, the graphite is burnt off, and the dirty light b residue is fused with acid sulphate of potassium; the fused mass dissolved in water; and the solution boiled, whereupon titanic anhydride is precipitated n pure. Part of the titanium is, however, dissolved by the acid together with the hence, to obtain the entire amount, the solution obtained by fusing the residue the silica with acid sulphate of potassium must be added to the iron solution, the sulphur contained in it has been precipitated as a barium-salt, and the exc baryta removed. The solution in which the titanium and phosphorus are to b termined, is first reduced with sulphite of sodium, and the excess of sulphurous driven off. It is then nearly neutralised with ammonia, and acetate of sodiu ammonium added. If there is only a small quantity of phosphoric acid present, will always be sufficient ferric oxide to precipitate it; but if not, a few drops of acid must be added, and the solution boiled and filtered as quickly as pos This precipitate may be at once treated; or if it contains much ferric oxi excess of that sufficient to form phosphate of iron, it is better to redissolve hydrochloric acid, reduce it again with sulphite of sodium, and repeat the oper above described. The precipitate is then dissolved in hydrochloric acid, and chl of magnesium, ammonia, chloride of ammonium, and tartaric acid added, the pr tate produced being allowed to stand two nights; then the ammonio-magne phosphate is filtered off, dried, ignited, and weighed, and the phosphoric acid calcu from the pyro-phosphate of magnesium. The filtrate from the phosphoric ac treated with sulphide of ammonium, and the sulphide of iron separated, the fi evaporated to dryness, ignited, and burnt in a muffle; or evaporated nearly to dry transferred to a flask, and treated with fuming nitric acid until all the tartaric is destroyed; in either case, the residue is fused with acid sulphate of potassium. fused mass is dissolved in cold water, boiled for some hours, and allowed to st night in a warm place, when the titanic acid is filtered off and washed with sulphuric acid—dried, ignited, and weighed. If the determination of phosphori is not required, then the precipitate produced (either by one treatment or two) b alkaline acetate, may be dried (without washing), burnt, and fused with acid sul of potassium, and dissolved in cold water, whereby a little phosphate of iron, remains insoluble, is separated; and the solution being boiled, the titanic acid i cipitated, and may be separated as before. (For further details, see the paper referred to.)

Tungsten, which sometimes occurs in the residue of the solution of iron in h chloric acid, may be rendered soluble by fusion with alkaline carbonate, and sepa by precipitation with acids or with mercurous nitrate. It may be separated fro other constituents of the iron by the solubility of tungstic acid in ammonia, or sulphide in sulphide of ammonium.

14. *Estimation of the Iron.*—The amount of pure iron in carburetted iron is gen determined merely by difference, after all the other constituents have been estim It may, however, be estimated directly by Fuchs' method with metallic copper (p. or by any of the volumetric methods hereafter to be described. Mohr recom especially the use of two titrated solutions of chromate of potassium, one ten more dilute than the other (p. 384).

IRON, CHLORIDES OF. Iron forms with chlorine two compounds, anal to the bromides.

Ferrous Chloride, $FeCl^2$, is obtained in the anhydrous state:—1. By p chlorine or hydrochloric acid gas over iron filings or turnings heated to redne gun-barrel connected with a receiver into which the product may sublime.— heating iron-filings with sal-ammoniac, ferrous chloride then remaining beh 3. By boiling down a solution of iron in hydrochloric acid out of contact with t and heating the residue till the water is expelled.

Ferrous chloride crystallises in white or yellowish-white shining scales, according to Senarmont, are six-sided, and optically uniaxial; it has a specific g of 2·528, melts at a red heat, and sublimes when more strongly heated in a close Heated in an atmosphere of *hydrogen*, it is reduced, yielding hydrochloric aci pure iron crystallised in tubes. Heated in dry *air* or *oxygen gas*, it is resolve ferric oxide and chloride, the latter volatilising:

$$3FeCl^2 + O^3 = Fe^2O^3 + 2FeCl^3.$$

In contact with *aqueous vapour* at a red heat, it gives off hydrogen and hydro acid, and is converted into ferroso-ferric oxide:

$$3FeCl^2 + 4H^2O = Fe^3O^4 + 6HCl + H^2.$$

It absorbs *ammonia-gas* at ordinary temperatures, swelling up and crumblin

Digitized by Google

powder, which, when exposed to the air, quickly takes up water and oxygen, is converted into ferric oxychloride and ferrico-ammonic chloride. Ferrous ide, heated to redness in dry ammonia gas, is converted into a nitride of iron, , containing 9·3 per cent. nitrogen (Frémy, Compt. rend. iii. 323). When d with a little charcoal powder, it is reduced by zinc-vapour at a red heat, yielding alline metallic iron, sometimes in dendrites, sometimes in tetrahedrons, and of fic gravity 7·84. (Ponmarède, Compt. rend. xxix. 520.)

rrous chloride exposed to moist air, absorbs water, and deliquesces. It dissolves r in *water* and *alcohol*, but is insoluble in *ether*. It dissolves in 2 pts. water at ° (Abl, Oesterreich. Zeitschr. f. Pharm. viii. 20); in 1 pt. of strong alcohol at . (Wenzel.)

drated Ferrous chloride, $FeCl^2.4H^2O$, is most easily obtained by dissolving iron ueous hydrochloric acid, finally heating the solution with excess of metal, and ing it at the boiling heat into a vessel moistened with strong hydrochloric acid. bluish-green liquid, left to cool in well-closed vessels, deposits the hydrated ide in crystals, which must be quickly pressed between paper and dried in air at t 30°. The bluish crystals are monoclinic, and cleave parallel to $\infty P\infty$ and $+P$. fic gravity, 1·937. The salt may be obtained as a crystalline powder by concen- ng the solution in a flask or a retort, and evaporating the concentrated liquid over ater-bath to a paste, stirring till it is cold. The crystals heated in a close vessel give off half their water, and the remainder at a higher temperature; when ly heated, they melt in their water of crystallisation; they effloresce at ordinary eratures when kept over oil of vitriol. They dissolve in 0·68 pts. *water*, easily in *ol* and, according to most authorities, in *ether*; according to Jahn, however, they soluble in ether. The solutions, especially the alcoholic, absorb *nitric oxide* gas, ssume a black-brown colour. The aqueous solution yields by *electrolysis*, iron and gen at the negative, chlorine and oxygen at the positive pole.

rrous chloride forms double salts with the chlorides of the alkali-metals. A ire of the concentrated solutions of ferrous chloride and *chloride of potassium* s, by cooling or slow evaporation, the salt, $K^2Fe''Cl^4.2H^2O$ or $2KCl.FeCl^2.2H^2O$, in blue-green monoclinic crystals. A similar *ammonium-salt* is obtained by mixing orresponding solutions, or by boiling iron filings with sal-ammoniac, hydrogen mmonia being then set free.

rric Chloride. *Trichloride of Iron*, Fe^2Cl^6, also called *Perchloride of Iron*, *sublimate*.—This compound is sometimes found in the craters of volcanos; it be obtained artificially by the following processes:—1. A piece of iron wire watch-spring introduced red-hot, or with a piece of burning tinder at the nto chlorine gas, burns with a red glow and forms ferric chloride, which then nes. The same result may be obtained by passing chlorine gas over gently d iron.—2. Ferrous chloride heated in chlorine gas is converted into ferric ide.—3. When ferrous chloride is heated in a vessel containing air, ferric chloride mes, and ferric oxide remains behind.—4. When an aqueous solution of ferric ide is evaporated, the dry compound remains behind, mixed with more or less ferric hloride; the dry residue, gently ignited in a loosely closed flask, yields the ferric ide sublimed in laminæ.—5. A mixture of 1 pt. calcined ferrous sulphate, and chloride of calcium, is ignited in a flask till the ferric chloride sublimes. (Baur, rt. Pharm. xxv. 432.)

rric chloride forms iron-black, iridescent plates, having a metallic lustre, and ilising and subliming somewhat above 100°. When heated in contact with *oxygen* it yields ferric oxide and chlorine; heated with aqueous vapour, it forms ferric e and hydrochloric acid gas. With *sulphuric acid* and with *sulphur*, it behaves ferrous chloride. (A. Vogel.)

ydrated Ferric chloride.—Ferric chloride dissolves in water with considerable ation of heat, and likewise deliquesces in the air. The liquid formed by deli- cence is called *Oleum Martis*. The same solution may be obtained by the wing methods:—1. By dissolving ferric oxide or its hydrate in boiling hydrochloric —2. By dissolving iron to saturation in a definite quantity of hydrochloric acid; ing the solution, and mixing it with half as much hydrochloric acid as it already ains; then heating the liquid to ebullition in a capacious vessel, and adding nitric in small portions, till the dark-brown colour first produced by the absorption of us gas has given place to a yellowish-brown, and the further addition of nitric produces no evolution of nitrous gas. The mixture is very apt to froth over, ially towards the end of the operation, when all the nitric oxide which has been rbed has been evolved. The same result may also be obtained by dissolving iron in muriatic acid; but it is not easy to hit the right proportion of the a ds.—3. By ng washed chlorine gas through aqueous hydrochloric acid saturated with iron, ng as the gas is absorbed. The dark brown liquid, which has a rough taste and

Digitized by Google

colours the skin yellow, yields, on evaporating and cooling, crystals containing t perhaps three different proportions of water.

α. *Dodeca-hydrated*, $Fe^2Cl^6.12H^2O$ (with 40 per cent. water).—Ferric chloride quesces rapidly in the air, then crystallises in the form of this hydrate, and after deliquesces much less quickly (Kinast, Kastn. Arch. xx. 281). The same hy likewise separates slowly from an aqueous solution of the chloride not too muc centrated—fine radii stretching out in all directions from particular points, and fo pale orange-yellow, opaque, hemispheric nodules, into which the whole liqu ultimately converted. If the evaporation has been carried too far, the syrup wi crystallise unless it be exposed for some time to the damp air of a cellar, from it can absorb water. (Mohr. Ann. Ch. Pharm. xxix. 173.)

β. A *penta-hydrate*, $Fe^2Cl^6.5H^2O$ (with 21·7 per cent. water) is obtained by eva ing the liquid to a syrup, mixing it with a small quantity of strong hydrochloric to re-dissolve the precipitated ferric oxychloride, and leaving it to itself in the (Stein, Repert. Pharm. xiii. 264).—2. By fusing the crystals α, evaporating ti liquid becomes perfectly solid on cooling, replacing the lost hydrochloric acid leaving the solution to cool (Fritzsche).—3. The crystals α, placed beside vitriol, under a receiver containing air, soon deliquesce and form a thick liqu which large crystals then form, till the whole is converted into a mass of cr (Fritzsche, J. pr. Chem. xviii. 479). The 5-hydrate forms flat roseate or reddish-yellow crystals, which fuse readily, and solidify again at 42°; they a water from the air very rapidly, and with evolution of heat (Fritzsche). Whe crystals α and β are shaken together, a slight fall of temperature takes place, liquid is obtained—the same as that produced by imperfect evaporation of the cr α—which produces great heat when mixed with water (Fritzsche). 1 at. chloride dissolved in 9 at. water yields a liquid, which is identical with the *Martis* of the older chemists (as obtained by deliquescence of the solid chloride i air), has a density of 1·545, and refuses to crystallise. Hence there are two solu of ferric chloride in water to be distinguished; one containing more than 5 and less 12 at., the other containing more than 12 at. water.

Hex-hydrate, $Fe^2Cl^6.6H^2O$ (with 25 per cent. water)?—The hydrate is obt according to Wittstein, by leaving a solution of ferric chloride concentrated to a de of 1·50 in a covered plate, standing in a cool place, till it solidifies to a ma rhombic plates; also by evaporating to a syrup and leaving it in a covered vessel warm place. According to Gobley, Mohr, and Fritzsche, however, highly concent solutions of ferric chloride always yield the $\frac{5}{2}$-hydrate.

Hydrated ferric chloride dissolves easily in *alcohol* and *ether*, forming yellow tions, in which, however, if exposed to light or heat, especially in the ethereal solu it is easily reduced to ferrous chloride. Ether abstracts it from the aq solution.

Ferric chloride is also easily reduced to ferrous chloride by *zinc*, *stannous chl* *sulphurous acid*, *sulphydric acid*, &c. *Hydriodic acid* reduces the concentrated not very dilute solutions of ferric chloride. *Silver* and *platinum*, immersed in the tion, are converted into chlorides, reducing the ferric to ferrous chloride. The redu is likewise effected by many *organic bodies*. The reducing action of *tartaric ac* ferric chloride has been applied to photographic purposes by Poitevin. (Compt. lii. 94.)

A concentrated acid solution of ferric chloride yields by *electrolysis*, ferrous chl at the negative pole, while chlorine, and a small quantity of oxygen are evolved a positive pole. Liebig has suggested the use of this solution, instead of nitric in the zinc-carbon battery; the zinc, according to Buff, should then be immers solution of common salt. Such a circuit is, however, less powerful than th Bunsen.

Ferric chloride is much used in medicine; it is a powerful styptic, and is empl in the treatment of aneurisms and varicose veins. A few drops of the aqueous sol quickly coagulate albumin. (Handw. d. Chem. ii. [3] 607.)

Basic Ferric Chloride, or *Ferric Oxychloride*.—When a solution of ferric chlor evaporated, hydrochloric acid, resulting from mutual decomposition of the ferric ch and water, is always given off at a certain degree of concentration; at the same ti certain quantity of undecomposed ferric chloride volatilises, and a basic salt i consisting of ferric chloride with more or less ferric hydrate. The stronger the centration, the greater is the quantity of basic salt in the residue. The evapo mass no longer dissolves clearly in water, unless hydrochloric acid is added to reco the ferric hydrate into chloride. If the temperature be raised very high durin evaporation, a considerable quantity of ferric chloride is evolved, and a highly insoluble salt remains behind. A solution of ferric chloride heated to 300° in a s tube, deposits ferric oxide. (Senarmont.)

Digitized by Google

of variable constitution are likewise obtained by ex-
ride to the air; by precipitating a solution of ferric
i not sufficient to take up the whole of the chlorine;
ith metallic chlorides, chloride of sodium for example,
, give off water, and afterwards ferric chloride, leaving

basic chlorides, are obtained by adding recently pre-
as ferric chloride. The hydrate dissolves in consider-

A larger quantity of water dissolves th but, on evaporation, colourless crystals of chloride of potassium separate out afterwards coloured crystals of the ferrico-potassic chloride; and at this concentration, the crystals of chloride of potassium redissolve without any wa stirring, and are reconverted into crystals of ferrico-potassic chloride. (Fri J. pr. Chem. xviii. 483.)

Ferrico-sodic Chloride melts at 200°, forming a very mobile liquid. (Dev

Ferrico-ammonio-potassio-sodic Chloride—$4(NH^4; K; Na)Cl.Fe^2Cl^6.2H^2O$ (co 12·1 per cent. potassium to 6·2 ammonium and 0·16 sodium)—is found, toget sublimed ferric chloride, in the craters of volcanos, and remains, after the re the ferric chloride by deliquescence, in ruby-red regular octahedrons, which dried over oil of vitriol. It is very deliquescent, and difficult to recrystallise decomposition. (Kremers, Pogg. Ann. lxxxiv. 79.)

IRON, CYANIDES OF. (See CYANIDES, ii. 221.)

IRON, DETECTION AND ESTIMATION OF.—1. *Blow-p actions.*—Iron-salts fused in small quantity, with borax on platinum wir outer flame, colour the bead yellow while hot, the colour disappearing on With a larger proportion of iron, the bead is red while hot, and yellow after In the inner flame a bottle-green glass is produced. With phosphorus-salt, moderate quantity of iron-salt is added, the bead is reddish-yellow in the ou while hot, becoming yellow as it cools, then green, and finally colourless. large proportion of iron, the bead is deep red while hot, becoming red-brown green as it cools, and reddish-brown when quite cold. The colours change b much more quickly than those of the borax bead. These reactions are co ferrous and ferric compounds (H. Rose). Ferrous oxide in minerals may be distinguished by heating the substance for a very short time in the inner fl a bead of borax coloured pale blue by a small quantity of oxide of copper; th oxide then reduces the cupric oxide to cuprous oxide or metallic copper, whi red spots on the bead. The heat must not be too long continued, as in t ferric oxide, if present, would be reduced to ferrous oxide, which would then pr reaction just mentioned. To check this result, a portion of the substance may b for a moment in the oxidising flame with a new borax bead containing cop bead will then assume a pale green colour if ferric oxide is present, whereas oxide would produce the red spots in this case also. (Chapman.)

2. *Reactions in Solution.*

Some compounds of iron are soluble in water, and the greater number are s acids; many, however, especially native ferric oxide, and the artificially prepar after strong ignition, require prolonged boiling with strong hydrochloric acid to them. The solution of many iron ores, and of ferric oxide in a state of ve aggregation, may be facilitated by addition of zinc or stannous chloride, which the ferric to ferrous oxide. Many iron ores can be rendered soluble only by fusi with alkaline carbonates; some only by fusion with acid sulphate of potassium o

Iron usually exists in solution as a ferric or ferrous salt, or partly in one sta in the other; rarely as ferric acid, on account of the great instability of the that acid.

Ferric salts in solution are mostly yellow or reddish-yellow, more rare the case of the iron-alums) colourless or pale violet. *Sulphydric acid gas* pa the neutral or acid solution of a ferric salt reduces it to a ferrous salt, with prec of sulphur, thus:

$$Fe^2Cl^6 + H^2S = 2HCl + 2FeCl^2 + S.$$

In a solution of neutral or basic ferric acetate, however, sulphydric acid form precipitate of sulphide of iron; if, on the other hand, the liquid contains fr acid, nothing but a milky precipitate of sulphur is produced.

Sulphydrate of ammonium produces, in neutral solutions of ferric salts, precipitate of sulphide of iron insoluble in excess of the precipitant, and b red-brown by oxidation in contact with the air. If the quantity of iron presen

Digitized by Google

inute, no precipitate is formed at first, but the liquid acquires a green colour, and if ept for some time in a closed vessel, deposits sulphide of iron in black flocks.

Alkalis and *alkaline carbonates* produce a red-brown precipitate of ferric hydrate soluble in excess of either of these reagents.

The *carbonates of barium, strontium,* and *calcium,* shaken up with a ferric solution, kewise form a precipitate of ferric hydrate.

Phosphate of sodium forms a white precipitate of ferric phosphate, which is turned ed-brown by alkalis, dissolves easily in nitric or hydrochloric acid, but is insoluble in cetic acid.

Ferrocyanide of potassium forms a deep blue precipitate of Prussian blue, insoluble acids, but dissolving in alkalis, with separation of ferric oxide. If the quantity of on present is very small, the precipitate appears green, or the liquid merely acquires green colour, and deposits blue flocks on standing.

Ferricyanide of potassium forms no precipitate, but changes the colour of the liquid greenish-brown. If the least trace of a ferrous salt is present, a blue precipitate is roduced.

Sulphocyanate of potassium changes the colour of ferric salts to deep blood-red, the oloration being very decided even in extremely dilute solutions: this is, in fact, the ost delicate of all tests for the presence of iron in the ferric state. The red colour is ot modified by addition of a small quantity of hydrochloric acid; but a large quantity early destroys it. A certain quantity of nitric acid destroys it completely after a hile, and it is not restored by subsequent addition of the ferric salt. The red colour is lso destroyed by oxalic, iodic, phosphoric, and arsenic acids, but reappears on again dding a solution of a ferric salt. Ammonia instantly decolorises the red solution and recipitates ferric hydrate. Sulphide of ammonium forms a black precipitate of ferric ulphide.

Infusion of galls colours ferric solutions deep blue-black, and renders them turbid. he precipitate is dissolved and the colour destroyed by free acids.

Ferric salts are easily reduced to ferrous salts by various *de-oxidising agents;* as by ulphydric acid, as already mentioned; by sulphurous, hyposulphurous, and phosphorous cids; by stannous chloride; by metallic iron, and even by silver at the boiling eat.

The reactions with sulphide of ammonium, alkalis, ferro- or ferri-cyanide of potas- ium, and sulphocyanate of potassium, serve to distinguish ferric salts from all other netallic salts.

Solutions of ferrous salts have a bluish-green or bluish colour, and, when xposed to the air, take up oxygen and are converted wholly or partially into ferric alts; and unless a sufficient excess of acid is present to form a neutral ferric salt with he quantity of iron present, part of the iron is precipitated in the form of a yellow- rown basic salt. They are likewise converted into ferric salts by *aërated water,* by *ypochlorous acid, nitric acid,* and by easily reducible metallic oxides and salts, such s those of *silver, gold,* and *mercury.* When nitric acid is the oxidising agent, the itric oxide separated from it does not escape from the liquid at ordinary temperatures, o long as any portion of ferrous salt remains unoxidised, but remains dissolved, forming dark greenish-brown solution.

A concentrated solution of ferrous sulphate or chloride placed in the circuit of a owerful voltaic battery, deposits metallic iron in small granules on the negative latinum wire. If the positive wire is dipped into a solution of common salt separated rom the iron solution by moist clay, the iron is obtained in glittering crystals which xhibit magnetic polarity (Becquerel). *Zinc* immersed in a perfectly neutral solution f ferrous sulphate or chloride contained in a stoppered bottle, throws down metallic ron (together with oxide) which is deposited partly on the zinc, partly on the con- iguous side of the glass. (Fischer, Pogg. Ann. ix. 266.)

Sulphydric acid forms no precipitate in a solution of ferrous salt containing an excess f one of the stronger mineral acids, but from a solution containing only a weaker acid, uch as carbonic, oxalic, tartaric, or acetic acid, it precipitates part of the iron, in the orm of a black hydrated ferrous sulphide, the precipitation in the three last-mentioned alts going on only till a moderate portion of acid is set free; the same reagent pre- ipitates ferrous benzoate, and even, to a slight extent, the sulphate and chloride, if he acids are completely saturated with base. From the sulphate or chloride mixed vith acetate of potassium, it throws down a considerable portion of the iron, but not he whole, even when the acetate is in excess. The black precipitate acquires a rusty rown colour by exposure to the air. It dissolves readily in hydrochloric or sulphuric cid, and likewise in a large quantity of acetic acid, provided it does not contain excess f sulphur.—The same precipitate, but containing the whole of the iron, is produced in ll ferrous salts, on the addition of an alkaline *sulphydrate,* and it is not soluble in an xcess of the reagent. A very dilute iron-solution to which sulphydrate of ammonium

Digitized by Google

is added, assumes a green colour, from the presence of iron-sulphide in a sta suspension.

Fixed caustic alkalis completely precipitate the iron in the form of a white hyd which, by exposure to the air, acquires a dingy-green and afterwards a red-b colour.—*Ammonia* throws down part of the iron in the form of hydrate, the remaining dissolved in the liquid, which, when exposed to the air, becomes cov first with a green and afterwards with a brown film. If the ferrous salt is previ mixed with sal-ammoniac, ammonia yields no precipitate, but forms a pale-g mixture which exhibits similar appearances on exposure to the air.

Monocarbonate of potassium or *sodium*, and *sesquicarbonate of ammonium*, t down white ferrous carbonate, which soon acquires a green and afterwards a b colour by exposure to the air, and, if sal-ammoniac be added, dissolves in the li which then exhibits a green, and subsequently a brown turbidity on exposure t air. *Acid carbonate of potassium* or *sodium* forms the same precipitate, with evol of carbonic anhydride; but, if the solutions are dilute, a clear mixture is formed, v deposits ferrous carbonate on boiling, and on exposure to the air yields a precip of ferroso-ferric hydrate.—The *carbonates* of *alkaline earth-metals* do not precip ferrous salts. (Fuchs.)

Phosphate of sodium precipitates white ferrous phosphate, which acquires a bl green colour by exposure to the air.—*Arsenate of sodium* precipitates white fe arsenate, which becomes dingy-green on exposure to the air.

Oxalic acid and *acid oxalate of potassium* communicate a yellow colour to fe salts, and, after a while, throw down yellow ferrous oxalate, the precipitation i immediate when an alkaline oxalate is used.

Ferrocyanide of potassium forms a precipitate which is white, if the solution been perfectly freed from air by boiling and the iron-salt is absolutely free from oxide, but otherwise bluish-white: by exposure to the air, this precipitate is verted into Prussian-blue. *Ferricyanide of potassium* gives a deep blue precip (ii. 244), even in very dilute solutions.

Sulphocyanate of potassium neither alters the colour of ferrous solutions, nor f any precipitate in them.

Tincture of galls neither colours nor precipitates ferrous salts when they are free from ferric oxide; but the mixture acquires a violet-black colour on exposu the air.

The preceding reactions, especially those with the alkalis, and with ferrocya ferricyanide, and sulphocyanate of potassium, afford marked distinctions bet ferrous and ferric salts; it is but rarely, however, that ferrous solutions can be obt so pure as to give the reactions exactly as they are above described, exposure t air for a very short time being sufficient to convert a portion of the ferrous into salt: hence the precipitate formed by ferrocyanide of potassium is generally some bluish, and those formed by the alkalis have more or less of a dark-green t The best way of obtaining a solution of iron quite free from ferric salt, is to imm a few pieces of bright iron wire in aqueous sulphurous acid: a mixture of fe sulphite and hyposulphite is then formed, which gives a perfectly white precip with ferrocyanide of potassium.

Solutions containing both ferrous and ferric salts, such as are obtained by disso magnetic oxide of iron in hydrochloric acid, of course give reactions interme between those of pure ferrous and pure ferric salts; in particular, they give blue cipitates both with ferrocyanide and with ferricyanide of potassium; the formati both these precipitates in a solution obtained by dissolving a mineral in hydroch or sulphuric acid, without the addition of any oxidising agent, such as nitric may be taken as an indication that the mineral contains a mixture or compou ferrous and ferric oxides. From such mixed solutions, the ferric oxide may be cipitated by means of carbonate of barium, while the ferrous oxide will rema solution.

For the reactions of iron in the state of ferric acid, see ii. 637.

3. *Quantitative Estimation of Iron.*

Iron is always estimated by weight in the form of ferric oxide. If the solution tains ferrous oxide, either alone or mixed with ferric oxide, it is first boiled w sufficient quantity of nitric acid to convert the whole of the ferrous oxide into oxide, and then treated with *ammonia* in excess to precipitate the latter. The pr tate is collected on a filter, washed, dried, and ignited at a moderate red heat high a temperature expels a portion of the oxygen. Every 10 pts. of pure oxide correspond to 7 pts. of metallic iron. In some cases, however, it is nece to use *potash* as the precipitant. In that case, the precipitated ferric oxide is ver

Digitized by Google

arry down with it a portion of the potash, which is exceedingly difficult to remove washing. It is best therefore, after having washed it two or three times with hot er, to redissolve it in acid and precipitate by ammonia. In other cases, as when the tion contains organic matter, the iron must be precipitated by *sulphide of ammonium*, use such substances prevent the precipitation of the oxide. To ensure complete ipitation, the liquid, after being mixed with excess of sulphide of ammonium, should eft for some time in a covered vessel standing in a warm place till it becomes quite urless or yellow, then filtered as quickly as possible, protecting it from the air, and precipitate washed with water containing sulphide of ammonium. The precipitated hide is then dissolved in nitric acid, and the iron precipitated by ammonia as before. the iron is mixed or combined merely with volatile or with easily combustible tances, its amount may be determined by simple ignition in contact with the air; he volatile and combustible matters will then be driven off or burnt away, and the will be left in the form of ferric oxide: to ensure its complete conversion into oxide, however, the residue should be moistened with nitric acid, and heated n.

n indirect method of estimating iron, given by Fuchs (J. pr. Chem. xvii. 160), nds upon the fact that metallic *copper* does not dissolve (or dissolves but very ly, and only when finely divided, ii. 40) in hydrochloric acid, if kept from contact the air, but when boiled with ferric chloride, it dissolves, with formation of us and cuprous chlorides:

$$Fe^2Cl^6 + Cu^2 = 2FeCl^2 + Cu^2Cl^2.$$

ne solution of ferric chloride mixed with excess of dilute hydrochloric acid and ed with water, is boiled in a flask, and clean copper-foil, not too thin (from 15 to ts. copper to 2 or 3 pts. ferric oxide), is completely immersed in the liquid; the is closed with a perforated cork, having a narrow glass tube passing through it, the liquid is boiled till it becomes permanently bluish-green or colourless. It is left to cool with the flask closed; decanted from the undissolved copper; this er washed by repeated affusion with hot water, and decantation, then dried between lous paper, and finally by heat, taking care not to rub it, and weighed. The loss eight multiplied by 0·883 gives the quantity of iron in the solution: for each atom pper (= 63·4) represents 1 at. iron (= 56) in the solution, and $\frac{56}{63·4} = 0·884$. Or oss of weight multiplied by $\frac{80}{63·4} = 1·261$ will give the quantity of ferric oxide ne solution. To ensure the complete reduction of the ferric to ferrous chloride, essential that the air be entirely excluded from the vessel, and therefore that the ng be kept up uninterruptedly till the liquid has become colourless.

lver in the spongy state may also be used to reduce the ferric chloride. The ucts of the reaction are ferrous chloride, which remains in solution, and chloride lver, which mixes with the metallic silver, and increases its weight. As in this ion, each atom of chlorine that enters into combination with the silver corresponds at. iron ($Fe^2Cl^6 + Ag^2 = 2FeCl^2 + 2AgCl$), the increase of weight multiplied by = 1·5774 gives the quantity of iron in the solution; or $\frac{80}{35·5} = 2·2535$ gives uantity of ferric oxide.

ne method of reduction by copper or silver may be applied to determine the quan- s of ferrous and ferric oxides, when they exist together in solution. The quantity rric oxide, or of iron existing as ferric salt, is first determined as above, the us salt present not interfering with the reaction. It is necessary, however, to d against the conversion of the ferrous into ferric salt by atmospheric oxidation: which purpose it is best to perform the determination in an atmosphere of nitrogen rbonic anhydride. Another portion of the solution is then treated with chlorine nvert the ferrous salt contained in it into ferric salt, and in this solution the total ntity of iron is determined by the same method. The difference of the two deter- ations gives the quantity of iron existing as ferrous salt.

errous and ferric oxides may likewise be separated by means of *carbonate of barium arbonate of calcium*, which precipitates ferric oxide from slightly acid solutions, not ferrous oxide. It is necessary to have the solution slightly acid, since if it is ectly neutral, a small quantity of ferrous oxide may likewise be precipitated. The tion, which should be slightly warmed, is shaken up with recently precipitated onate of barium (which acts more quickly than carbonate of calcium), in a corked k filled with carbonic anhydride; then left to stand, and shaken up again from e to time, till it has become quite colourless, afterwards filtered, and the precipitate hed, always in an atmosphere of carbonic anhydride. The precipitate, consisting

Digitized by Google

of carbonate of barium mixed with ferric hydrate, is dissolved in dilute acid, the baryta precipitated by sulphuric acid, and the ferric oxide from by ammonia. This determines the quantity of iron existing in the solut *cum*. To find the quantity existing as *ferrosum*, the liquid filtered from tate of carbonate of barium and ferric oxide is boiled with nitric acid, to ferrous into ferric salts, then freed from baryta by sulphuric acid, and the cipitated as ferric oxide by treating the filtrate with ammonia. Or an of the original solution may be treated with nitric acid, to bring all the ferric state, and the total quantity of iron determined by precipitation wi The difference of the two determinations will then give the quantity of as ferrosum.

Anhydrous ferroso-ferric oxides may be analysed by dissolving them nitromuriatic acid, and precipitating the iron as ferric oxide by am proportions of iron and oxygen are thus determined, whence the for calculated.

Volumetric estimation of iron.—When iron is contained in a soluti oxide or ferrous salt, it may be estimated by determining the quantity of agent required to convert it into ferric oxide; if, on the other hand, it ferric oxide, the estimation may be made by measuring the quantity o agent required to bring it to the state of ferrous oxide.

1. *Methods depending on oxidation.*—The reagent most generally converting ferrous into ferric oxide in volumetric analysis is *permanganate* The method of applying it is fully described in the article ANALYSIS, (i. 263).—If the iron in the solution under examination is present wholly the method is directly applicable; if, on the contrary, the iron is pres partly as ferricum, it must first be brought to the ferrous state by he sulphurous acid or sulphite of sodium, or better with a few grains of pur mixture of ferrous and ferric salts, the ferrosum may be determined by portion with the permanganate directly, and another after reduction of t in the manner just described.

Acid chromate of potassium may also be used for the volumetric estim and has the advantage of not varying in strength when its solution is closed vessels. The reaction between ferrous oxide and chromic acid m sented by the equation:

$$\underset{\text{Chromic anhydride.}}{2CrO^3} + 6FeO = 3Fe^2O^3 + \underset{\text{Chromic oxide.}}{Cr^2O^3}$$

whence we find that 1 grm. of iron requires 0·8849 grms. of acid chromate $K^2O.2CrO^3$, to convert it from ferrous into ferric oxide. If, then, 8· the pure acid chromate are made into a litre (1000 cub. cent.) of soluti cent. of this solution will correspond to exactly 1 grm. of iron. The s acid chromate is slowly added to the acid ferrous solution till a drop of longer forms a blue precipitate with red prussiate. (Penny, Chem p. 599.)

Bunsen (Ann. Ch. Pharm. lxxxvi. 288) adds to the ferrous solutio hydrochloric acid, a weighed quantity of acid chromate, more than suffi complete oxidation of the ferrous salt, passes the chlorine evolved on he solution of iodide of potassium, and estimates the quantity of iodine thus the method described under ANALYSIS, VOLUMETRIC (i. 265). If no f were present, 1 at. $K^2O.2CrO^3$ would give 3 at. chlorine, and therefore but as a portion of the chlorine is used up in converting the ferrous into there will be 1 at. less of iodine set free for every 1 at. iron present as The quantity of iron x will therefore be given by the formula:

$$x = \frac{3Fe}{K^2O.2CrO^3} \cdot p - \frac{Fe}{I} a(nt - t')$$

where p denotes the weight of acid chromate used, and a, n, t, t' have the cations as in the article just cited.

For the exact estimation of iron in cast iron, iron ores, &c., Mohr use solutions, one containing 8·785 grms. of the acid chromate in a litre, th cent. = 0·01 grm. iron; the second diluted ten times as much, therefor = 0·001 grm. iron. A quantity of the substance, containing about 1 grm (that is to say 1·05 grm. pig iron, or 2·00 grms. iron ore, supposing the tain about 50 per cent. iron) is then weighed out, and dissolved in hydr the whole of the iron in solution is brought to the ferrous state by reduct &c.; the solution is then mixed with 100 cub. cent. of the stronger solutio

4. *Separation of iron from other elements.*

From all metals of the first group (i. 217), iron is easily separated by *sulp acid*, which throws down all those metals, leaving the iron in solution. The which contains the iron in the form of ferrous salt, must then be heated with acid to oxidise the iron, which may afterwards be precipitated by ammonia.

The separation of iron from the metals of the second group, which are not preci by sulphydric acid from acid solutions, but are precipitated, together with i sulphide of ammonium from neutral or alkaline solutions, is more difficult.

From manganese (present as manganous salt) and from zinc, iron i effectually separated by *succinate* or *benzoate of ammonium*. The solution, af the iron has been brought to the state of ferric salt, is mixed with a sufficient q of sal-ammoniac to hold the manganese or zinc in solution, and very carefully neut with ammonia; it is then treated with benzoate or succinate of ammonium, which down the iron as ferric benzoate or succinate, leaving the manganese or zinc i tion. The precipitate is washed, dried, and ignited in an open platinum cruc that the air may have sufficient access to it, to prevent any reduction of the i the carbon of the organic acid. Should such reduction take place, the iron m reoxidised by nitric acid. The success of this mode of separation depends enti the care with which the acid in the solution is neutralised with ammonia before the benzoate or succinate. If too much ammonia has been added, manganese goes down with the iron; if too little, a portion of iron remains in solution addition of ammonia should be continued till a small quantity of ferric oxide cipitated, and does not redissolve on agitation. The supernatant liquid has deep brown colour, the greater part of the iron being still in the solution.

The separation of iron (as *ferricum*) from manganese and zinc may also be e by agitating the solution with *carbonate of barium* (as in the separation of ferri ferrous oxide, p. 383), which precipitates the iron as ferric oxide, leaving the metals in solution.

According to J. Schiel (Sill. Am. J. [2] xv. 275) manganese may be sep from iron by mixing the solution with *acetate of sodium*, and passing *chlorine* t it, which throws down the manganese as peroxide.

Zinc may be separated from iron (ferricum) when both are present as acetat solution containing a sufficient quantity of free acetic, but no inorganic acid, by p *sulphydric acid gas* through the solution, the zinc being then precipitated whi iron remains in solution. If the two metals are combined with any other acid must be precipitated by carbonate of potassium, and redissolved in acetic acid they are present as sulphates, they may be converted into acetates by decomp with acetate of barium.

For the methods of separating iron from cobalt, see vol. i. p. 1046. When t metals are precipitated together by sulphide of ammonium, the separation m effected by digesting the sulphides with acetic, as well as with dilute hydro acid; the iron then dissolves as acetate, while the cobalt remains behind.

Iron may be separated from nickel by the same methods as from cobalt (exc that with nitrite of potassium). Nickel may also be separated from iron (*fer* by mixing the solution with a large quantity of sal-ammoniac (20 pts. of that 1 pt. of nickel), precipitating the iron with *carbonate of ammonium*, then heati liquid slowly to the boiling point, keeping it at that temperature for some time, a small quantity of ammonia and filtering: ferric oxide then remains on the while all the nickel passes through in solution (Schwarzenberg, Ann. Ch. P xcvii. 216). Iron and nickel may also be separated by precipitating the iron as oxide with *carbonate of barium*. For the separation of iron from cobalt, this m is not so well adapted, because a small portion of the cobalt is apt to be precip at the same time.

Uranium may be separated from iron, both being in the state of sesquioxid treating the solution with excess of *carbonate of ammonium*, which precipitat ferric oxide, and retains the uranium in solution. The carbonate of ammonium however, be quite neutral, as if it contains any excess of carbonic acid, part of th may be redissolved. To ensure this condition, the carbonate of ammonium sho previously boiled, and the solution of the metals, if acid, must be neutralised ammonia till a slight permanent precipitate begins to form; the solution is to be diluted with water, the carbonate of ammonium added, and the preci digested with it for some time before filtering.

For the separation of iron from cerium, chromium, didymium, lantha molybdenum, niobium, platinum and its congeners, tantalum, titan tungsten, and vanadium, see those metals; also pp. 374, 375.

precipitates the iron as ferric oxide, and retains the alumina in solution.
portion of iron is small (not exceeding 1 pt. ferric oxide to 100 alumina),
d of separation is sufficiently exact; but when it is larger, a portion of the
lways remains with the ferric oxide, and must be separated by redissolving
itate in a small quantity of hydrochloric acid, and repeating the treatment
h. With very large quantities of iron, this treatment must sometimes be
hree or four times before complete separation is effected. The process may
d by first reducing the ferric solution with sulphurous acid or an alkaline
nd then boiling with potash till the iron is precipitated as dark green
ric oxide; but in this way also the separation is not quite complete; if too
hurous acid is added, a small quantity of sulphite of aluminium is sometimes
d on boiling.

d aluminium may, however, be much more easily separated by means of
ite of sodium, which precipitates alumina together with sulphur, leaving the
ution (i. 155).

very good method of separating iron and aluminium is to mix the solution
ntity of *tartaric acid*, sufficient to prevent the precipitation of the oxides
liquid is rendered alkaline, then add excess of ammonia, and precipitate the
phide by *sulphide of ammonium*. The same method serves to separate iron
us other metals, *e.g.* cerium, glucinum, magnesium, thorinum, yttrium, and

ium (or glucinum) may also be separated from iron by precipitating the
nd ferric oxide together with *ammonia*, and igniting a weighed quantity of
d and calcined precipitate in a stream of hydrogen. The iron is then
the metallic state, while the alumina remains unaltered. The loss of weight
quantity of oxygen which was combined with the iron, whence the quantity
xide may be calculated, and the alumina determined by difference. As a
he result, which is especially necessary when the quantity of iron is small,
e may be digested for 24 hours, without heating, in very dilute nitric acid
of specific gravity 1·2 diluted with more than 30 pts. water), which dis-
iron without attacking the ignited alumina. A slight loss may arise in this
consequence of particles of the alumina (or glucina) being carried over by
n of hydrogen (Rivot). Deville modifies this process by exposing the
f metallic iron and alumina, obtained as above, to a very strong red heat, in
f hydrochloric acid gas, whereby the iron is volatilised as chloride, while
na remains unaltered, and may afterwards be weighed; the iron is then
d by difference. Or the iron may also be directly determined by passing
r of boiling hydrochloric acid into the tube and attached receiver, in which
le of iron is condensed, oxidising the solution of ferrous chloride thus ob-
h nitric acid, and precipitating by ammonia.

glucina, and from most other protoxides, iron in the form of sesquioxide
parated by precipitation with carbonate of barium (p. 383).

magnesia, ferric oxide may be separated by precipitation with *ammonia* after
f sal-ammoniac—better with *succinate* or *benzoate of ammonium*, as already
for manganese (p. 386), or with *carbonate of barium*.

he alkalis and alkaline earths, ferric oxide may be separated by *am-*
the case of the alkaline earths, however, care must be taken not to add
a slight excess of ammonia, and to protect the precipitate from the air
tration and washing; otherwise carbonic acid will be absorbed, and earthy
s will be precipitated, together with the ferric oxide, and the precipitate,
ning, will appear light-coloured; it must then be redissolved in acid, and
ated by ammonia. If the solution contains any organic substance, the iron
recipitated by sulphide of ammonium (p. 383).

ation by ammonia serves to separate iron in the ferric state from most of its
salts, *e. g.* the nitrate, sulphate, &c. From phosphoric or boric acid it
parated by dissolving the salt in hydrochloric acid, adding tartaric acid in
quantity to prevent precipitation by alkalis, then adding excess of ammonia,
itating the iron by sulphide of ammonium.—For other methods of analysing
s of iron, see PHOSPHORIC ACID.

rsenic, iron may be separated by precipitation with *sulphydric acid*, the
r arsenate of iron being dissolved in hydrochloric acid. These salts may also
osed in the dry way, by ignition in a stream of sulphydric acid gas, sulphide
then volatilising, and sulphide of iron remaining. (See also p. 374.)

5. *Assay of Iron ores.*

1. *In the wet way.*—From most ferruginous minerals that are actually used fo extraction of iron, viz. the oxides and carbonates, the iron may be dissolved ou boiling with hydrochloric acid, the insoluble residue consisting of quartz, clay, which may be further analysed by fusion with an alkaline carbonate.

The acid solution generally contains—besides iron—manganese, aluminium, cal magnesium, the alkali-metals, and small quantities of sulphur, phosphorus, ar silicium, and titanium, and less frequently copper, zinc, lead, vanadium, chrom molybdenum, and tungsten. These elements may be detected and separated by me already described, or to be described, under their respective heads (see also pp. 3 376). The last four, together with titanium, may be separated by fusing the pulve ore with a mixture of alkaline carbonate and nitrate, and treating the fused mass water, whereby a solution is formed, which may contain titanate, vanadate, chro molybdate, and tungstate of alkali-metal, together with silicate, arsenate, and phosp

If the whole of the iron cannot be extracted from an ore by boiling with h chloric acid, it must be pulverised and fused with carbonate or acid sulphate of a metal (bisulphate of potash), and the fused mass then dissolved in water or aq acid, freed from silica by evaporation, and further examined for the above-ment constituents.

In the complete quantitative analysis of iron ores, it is necessary to determin water and carbonic acid. The water may be estimated by igniting the ore in a tube, and condensing the aqueous vapour by means of chloride of calcium; the car acid by the method described under ALKALIMETRY (i. 119). When either wat carbonic acid is present alone, its amount may be determined by the loss of w sustained on ignition.

If the percentage of iron in the ore is the only point to be determined, the iron, being brought into the ferric state by oxidation with nitric acid, may be precipi by ammonia, or, if phosphoric and arsenic acids are present, by sulphide of ammo after addition of tartaric acid (p. 387). Alumina, if present, must be separated b of the methods already described. All the trouble of these separations may, how be avoided by adopting Fuchs' method of estimation with metallic copper, which correct results, provided all necessary precautions are taken to exclude the air, one of the volumetric methods already described.

2. *In the dry way.*—The object of this mode of assaying, which is an imitatio the small scale, of the process which goes on in the blast furnace, is to determine only the quantity of iron contained in an ore, or rather the quantity that ca extracted by smelting, but likewise the quality of the pig iron obtainable, and gene also that of the slag.

10 grms. of the finely-pounded ore are mixed with 3 to 10 grms. of anhydrous b (according to the proportion of the gangue); and the mixture is placed in a cru lined with charcoal (*creuset brasqué*),* and exposed in a powerful air-furnace portable blast-furnace—Griffin's blast gas-furnace (ii. 787), for example—to a grad increasing heat, raised at last to whiteness. After cooling, there is found in crucible, if the operation is successful, a well-fused regulus of cast iron, and above slag composed of borax and the materials of the gangue. The regulus must be fully freed from slag and weighed. It should have a grey colour without appearance of separated graphite. A large separation of graphite shows that the has been too great. If the metal is white, it is very fusible and probably con manganese; it is then imperfectly carbonised, or it contains phosphorus, arseni sulphur. The slag should not contain either globules of iron mechanically m (these, if present, must be separated from the pulverised slag by levigation, or b magnet), or iron chemically combined, which latter condition will be indicated green colour in the slag. The weight of the regulus is increased by the carbon w it contains, but, on the other hand, a small quantity of iron always remains in the and the two errors thus produced may, for the most part, be regarded as compens one another.

Sometimes powdered glass free from metal is used instead of borax, to increas fusibility of the gangue; or the ore to be assayed is mixed with the same kind of that is to be used in the actual smelting process—that is to say, with chalk, i

* To prepare these crucibles, a Hessian or Cornish crucible is lined with successive layers of a composed of fine charcoal powder mixed with water, the whole being well stamped with a w pestle. As soon as a layer has been well pressed, its surface must be roughened with a knife, s the next layer may adhere to it well; otherwise the layers will separate when heated. The cr having been thus filled with stamped charcoal, the portion which projects over the edge is rem a cavity with rounded bottom is made in the middle, and the sides and bottom of this cavity are po with a rounded glass rod

right proportion of flux has been added, and the proper temperature attained, nstituted regulus is produced (p. 388), together with a good slag, having a owish or sometimes violet colour, an enamel-like or sometimes glassy aspect, choïdal fracture. If the slag is stony or earthy, yellow, grey, or brown, with cture, it is too rich in bases; too great an excess of lime causes it to crumble en touched. If, on the other hand, there is an excess of silica, the slag is ore or less transparent, of green colour (arising from ferrous oxide), and very The results of a successful assay yield the requisite data for smelting on the e.

6. *Atomic Weight of Iron.*

omic weight of iron has been determined in several ways:—1. From the ferric oxide obtained by dissolving a known quantity of pure iron (harpsire) in nitric acid, precipitating with ammonia, &c., the small quantity of ntained in the iron being estimated and allowed for.—2. From the quantity tained by reducing a known weight of ferric oxide with hydrogen.—3. By g the volume of hydrogen evolved in the solution of iron in hydrochloric acid. n the quantity of chloride of silver obtained by precipitating a known quanre ferrous or ferric chloride with nitrate of silver. The following table exhibits s obtained by various chemists; the determinations are arranged in chronolor, and the bracketed numbers indicate the method employed:

* (1) . . . Fe = 27·12	Berzelius§ (1) . . . Fe =	28·03

mber 27·12, deduced from the first experiments of Berzelius, was for many eived as the true atomic weight of iron, although Bucholz, some years d made a determination of the composition of ferric oxide, which now appears een nearer the truth. Berzelius was afterwards led to conclude that his first nts were affected with an error, arising from the action of the nitric acid on vessel used, and from subsequent experiments, in which platinum vessels loyed, he obtained the higher number 28·03. The whole number 28, which an of all the most trustworthy determinations, is now universally adopted as tomic weight of iron, on the supposition that the metal is univalent in the and sesqui-valent in the ferric salts, *e.g.* ferrous chloride = *FeCl*; ferric

chloride = Fe^2Cl^3. If, however, iron is supposed to be bivalent in the ferrou trivalent in the ferric compounds—which is the view now generally adopted, *e.g*

Ferrous chloride . .	$FeCl^2$	Ferric chloride . . .	$FeCl^3$
Ferrous oxide . . .	FeO	Ferric oxide . . .	Fe^2O^3,

then the atomic weight is Fe = 56. (See METALS, ATOMIC WEIGHTS OF; also i ii. 30.)

The equivalent of iron, that is to say, the quantity of the metal which re 1 at. of hydrogen, is, in the ferrous compounds, *e.g.* $FeCl^2$, equal to 28, and in the compounds, *e.g.* Fe^2Cl^6, or $FeCl^3$, it is $\frac{2}{3}$ of 28, or $18\frac{2}{3}$, which number is denoted (See EQUIVALENTS, ii. 403.)

IRON, FLUORIDES OF. *Ferrous fluoride*, FeF^2, is obtained by diss iron in aqueous hydrofluoric acid, and crystallises by evaporation, or as the so approaches saturation, in small, colourless, rectangular plates containing water, they give off without decomposition when moderately heated. The anhydrous fl is not altered by ignition, even in contact with the air, but the hydrated sal turns yellow on exposure to the air, and if quickly heated, oxidises partially, off hydrofluoric acid. The hydrated crystals dissolve slowly in pure water easily in acids. Ferrous fluoride forms with *fluoride of potassium* a soluble salt, $2KF.FeF^2$, which separates in granular crystals. (Berzelius.)

Ferric fluoride, Fe^2F^6, is obtained by dissolving ferric oxide or hydrate in a hydrofluoric acid, and separates on evaporation in pale flesh-coloured crystals. heated in a platinum crucible, over a lamp urged by a blast, it melts, som exhibiting on the surface small cubic crystals of the fluoride, while the fused ma a rose-red colour, perhaps due to the formation of a small quantity of ferric Ferric fluoride is isomorphous with fluoride of aluminium, somewhat more fusibl that compound, and equally volatile. (Deville, Compt. rend. xliii. 970.)

Ferric fluoride dissolves slowly but completely in water, forming a colo sweetish, astringent liquid. Its solution mixed with ammonia deposits a basic oxyfluoride, which, when dry, forms a rust-yellow powder.

Mixtures of the solutions of ferric fluoride and fluoride of potassium deposit, o cooling, colourless, crystalline, sparingly soluble double salts. If the solution ferric fluoride is added by drops to that of the potassic fluoride, the salt for $2KF.Fe^2F^6$, in the contrary case, $4KF.Fe^2F^6$. (Berzelius.)

IRON-GLANCE. *Specular Iron ore.* See IRON, OXIDES OF (p. 385); als (p. 338).

IRON, HYDRATES OF. See IRON, OXIDES OF (pp. 393—399).

IRON, HYDRIDE OF. The flame of hydrogen evolved by dissolving i dilute acids sometimes yields black spots when a cold piece of porcelain is held and has hence been supposed to contain a gaseous compound of iron and hydrog Fresenius and Schlossberger (Ann. Ch. Pharm. xliv. 264), and other che have shown that these spots are produced by phosphorus, and that the gas, perfectly freed from mechanical impurities, does not produce them. Cameron (News, ii. 181) has shown that no ferruretted hydrogen is formed by dissolvi alloy of iron and sodium in acids.

When ferrous iodide is treated with zinc-ethyl and ether, gas is evolved (con of hydride of ethyl and hydrogen), and the residue, after washing with ether, y hydride of iron, mixed with metallic iron, in the form of a black powd sembling metallic iron, and decomposing with evolution of hydrogen, in contac water, or when heated. (Wanklyn and Carius, Ann. Ch. Pharm. cxx. 74.)

IRON, IODIDES OF. *Ferrous Iodide*, FeI^2, obtained by heating or tritu iodine with a slight excess of iron filings, is a brown compound, which melts at heat, forms a grey laminar mass on cooling, and volatilises at a stronger he dissolves readily in water, and the pale green solution, which may also be directly by digesting 1 pt. iron and from 2 to 4 pts. iodine in water, yields evaporated in contact with iron, and protected from the air, green deliquescent cr containing $FeI^2.5H^2O$. Both crystals and solution, when exposed to the air quickly turn brown, from formation of oxyiodide, and separation of ferric hydra iodine. Ferrous iodide cannot, therefore, be easily kept unaltered, either in th state or in solution; it keeps best when mixed with a sufficient quantity of cr sugar or milk-sugar. For preparing the compound for medical use, Mohr recom that 1 pt. iodine be converted into ferrous iodide by trituration with iron and the filtered liquid mixed with 25 pts. of simple syrup, and the whole quickly evap down to 25 pts.; 20 pts. of this syrup contain 1 at. of ferrous iodide. It is

Digitized by Google

vever, to prepare the compound fresh every time it is wanted, which is not difficult, the action is very quick.

The solution of ferrous iodide treated with alkaline carbonates, yields iodides of the ali-metals, and may be used for the preparation of those compounds.

Ferrous iodide easily dissolves an excess of iodine: on adding 1 at. iodine to 3 at. rous iodide, a brown solution is formed (containing Fe^2I^6), which, when mixed with bonate of potassium, yields iodide of potassium and black ferroso-ferric hydrate; s doubtful whether the brown solution contains iodated ferrous iodide, or a ferroso-ric iodide, analogous to the magnetic oxide.

Ferric iodide, Fe^2I^6, is not known with certainty, but appears to be formed when n is heated in excess of iodine-vapour. The resulting compound dissolved in ter, yields a brown-red solution, which reacts like that which is obtained by dissolv- iodine in ferrous iodide, as above, or by dissolving ferrous hydrate in hydriodic acid. these solutions, when exposed to the air, give off iodine and deposit ferric hydrate.

IRON, METEORIC. See p. 336.

IRON, NATIVE. See p. 335.

IRON NATROLITE. See NATROLITE.

IRON, NITRIDE OF. Iron heated to dull redness in a porcelain tube, and bjected to the action of ammonia gas, becomes white, brittle, and increases in weight about 12 per cent. The compound thus formed is supposed by Despretz (Ann. im. Phys. [2] xlii. 122) to be a nitride of iron; but it has not been analysed, and is pposed by some chemists to contain hydrogen. It dissolves in weak acids, with olution of hydrogen and nitrogen, and formation of ammoniacal salts. At a white at it decomposed, giving off its nitrogen. Hydrogen, at a red heat, withdraws the trogen, forming ammonia.

Sometimes the iron, after ignition in ammonia-gas, is found to be altered in physical pperties, and yet not to have increased in weight; in such a case, the combination of e nitrogen with the iron is but transient, but nevertheless appears to alter its mo-ular structure.

Nitride of iron is also produced when oxide of iron is ignited in ammonia gas; also minute quantity when nitrogen gas is passed over red-hot iron. (Pelouze et rémy. *Traité*, ii. 452.)

Respecting the controversy about the existence of nitrogen in steel, see STEEL.

IRON, NITROSULPHIDES OF. *Nitrosulfures de fer.* (Roussin, Ann. n. Phys. [3] lii. 285.)—Compounds produced by the simultaneous action of nitrites d alkaline sulphides on iron-salts. They contain nitric oxide, together with sulphide iron and sulphide of hydrogen or an alkali-metal, and may therefore perhaps be garded as analogous in composition to the nitroferricyanides (ii. 250), that is to say, sulphides of iron in which 1 at. sulphur is replaced by 2 at. *nitrosyl*, NO. They ntain in fact a disulphide of iron, FeS^2, in which the fourth, or sometimes the half, the sulphur may be supposed to be replaced by an equivalent quantity of nitrosyl. e analogy of the nitrosulphides to the nitroferricyanides is shown by the fact, that nen a solution of nitroferricyanide of sodium is completely decomposed by sulphydric d, and the solution boiled and evaporated, the residue contains dinitrosulphide of n, which may be reconverted into a nitroferricyanide by treating it with cyanide of tassium. A mixture of iron-salt and nitrite of potassium yields a nitroferricyanide nen treated with cyanide of potassium, and nitrosulphide of iron when treated with lphide of potassium. In neither of these classes of compounds can the iron be tected by ordinary reagents.

Dinitrosulphide of Iron, $Fe^3S^3H^2(NO)^4 = Fe^2S^3(NO)^2.FeS.(NO)^2.H^2S$, or Fe^3S^4 $O)^4.H^2S$.—This compound is prepared by dropping a solution of ferric chloride or sul-ate, with constant stirring, into a mixture of the solutions of nitrite of potassium and lphide of ammonium, heating the liquid to boiling, keeping it at the boiling heat for a w minutes, and filtering to separate sulphur; the deep-coloured liquid deposits crystals the compound on cooling.—Or 35 grms. ferrous sulphate dissolved in 0·2 litre of de-rated water is added to a solution of 21 grms. dry nitrite of potassium, and 16 grms. ystallised sulphide of sodium also in 0·2 litre of water, and the solution is boiled and tered. When a ferrous salt is used in the preparation, no separation of sulphur kes place. The crystals are purified by recrystallisation.

Dinitrosulphide of iron forms black, needle-shaped, oblique rhombic prisms, 2 mm. ng, more soluble in hot (about 2 pts.) than in cold water, easily soluble in alcohol, ood-spirit, amylic alcohol, and glacial acetic acid; they dissolve in all proportions in her, and deliquesce even in ether-vapour. The solutions are very deep-coloured, ste styptic at first, then persistently bitter; they remain unaltered in air containing mmonia, and may be recrystallised from alkaline solutions. When heated to 115°—0°, they give off reddish vapours, together with sulphur, sulphite of ammonium, and

Digitized by Google

nitrite of ammonium, and leave iron in the residue; when quickly heated, th away. The compound is easily decomposed by mineral acids, with evolution of vapours, not by organic acids. Chlorine and iodine decompose it, with evolu nitric oxide and separation of sulphur. It is precipitated from solution by pot ammonia, much more slowly by soda. The crystals are decomposed by perma of potassium, peroxide of lead, and mercuric oxide. Many metallic salts pre the solution, with elimination of nitric oxide. Cyanide of potassium and cya mercury convert the crystals into nitroferricyanides.

The crystals are not decomposed by sulphide of ammonium, sulphydric acid or ferri-cyanide of potassium, or tannic acid, neither of these reagents givi indication of the presence of iron in them. Neither are they decomposed by potash or soda in the cold, but when heated therewith, they give off ammonia yield ferric hydrate, together with a filtrate which deposits the following comp

Sulphuretted Nitrosulphide of Iron and Sodium, $Fe^2Na^6N^2S^6O^2$ or $Fe^2S^3(NO)^2$ —This compound forms large black crystals having a very bitter taste, easily so water and in alcohol, but insoluble in ether. The crystals decompose at 120° solution is decomposed, with evolution of nitric oxide, by chlorine, iodine, or n oxide. It forms precipitates with metallic salts, the reaction being in som attended with evolution of nitric oxide. The solution yields crystalline compo addition of potash or ammonia, but is not altered by caustic soda; the cryst not altered by sulphide of ammonium or ferrocyanide of potassium, but with ferri of potassium they yield nitric oxide gas and prussian-blue.

Sulphuretted Nitrosulphide of Iron and Hydrogen, $Fe^2H^8N^2S^7O^2 = Fe^2S^3(NO)^2.4$ separates in reddish flocks, when the preceding compound is decomposed by ac gives off sulphydric acid and suffers further decomposition, even during washi

Nitrosulphide of Iron, $Fe^2S^3N^2O^2$ or $Fe^2S^3(NO)^2$, separates, with evolution phydric acid, when sulphuretted nitrosulphide of iron and sodium is decompose acid at the boiling heat. It is a black substance, which when freshly prepar dried, burns away like tinder, when set on fire. It decomposes spontaneously, sulphide of iron. It is insoluble in water, alcohol, and ether, but dissolves in potash, with partial decomposition and separation of ferric hydrate.

Nitrosulphids of Iron and Sodium, $Fe^2Na^2N^2S^4O^2.H^2O = Fe^2S^3(NO)^2.Na^2S$ Formed by evaporating a solution of nitrosulphide of iron in sulphide of sod 100°, and treating the residue with alcohol and ether. Crystallises in red black by reflected light; dissolves with deep red colour in water, alcohol, and et is insoluble in chloroform and in sulphide of carbon. The solution is precipit metallic salts, forming insoluble compounds in which the sodium is replaced other metal. Some of these precipitates are tolerably permanent, whereas oth silver precipitate for example, decompose quickly, with evolution of nitric oxid

IRON ORES. The ferruginous minerals containing sufficient quantities to be available for the extraction of the metal, have already been described (pp. 343). For the methods of assaying them, see p. 388.

The following mineralogical terms must here be noticed.

Argillaceous or Clay Iron Ore.—This term is applied to several ores consis oxide or carbonate of iron mixed with clay. The argillaceous carbonate is call ply "clay iron-stone;" anhydrous and hydrated ferric oxides with a similar adm are called "red clay iron-stone," and "brown or yellow clay iron-stone," respec

Azotomous Iron Ore, or *Kibdelophane*. A variety of ilmenite or titaniferou ore. (See TITANATES.)

Bog Iron Ore.—A brittle or loosely aggregated variety of brown hæmatite, oc in low marshy grounds. It proceeds from the decomposition of other species an takes the form of leaves, nuts, or stems, found in the marshy soil.

Brown Iron Ore.—Hydrated ferric oxide (p. 338).

Columnar Iron Ore.—Red clay iron stone, having a columnar structure.

Green Iron Ore.—Hydrated ferric phosphate. (See DUFRENITE, ii. 347.)

Jaspery Iron Ore.—A variety of red clay iron ore, having a large, flat conchoïdal fr

Lenticular Iron Ore.—A variety of red clay iron-stone having a flat granular str

Magnetic Iron Ore.—Ferroso-ferric oxide (pp. 337, 397).

Micaceous Iron Ore.—Specular iron ore with a micaceous structure.

Ochreous Iron Ore.—Red hæmatite, having a soft earthy consistence.

Octahedral Iron Ore.—Syn. with magnetic iron ore.

Pitchy Iron Ore.—A variety of red hæmatite.

Red Iron Ore.—Native ferric oxide (p. 337).

Sparry or Spathic Iron Ore.—Crystallised ferrous carbonate (i. 785).

Specular Iron Ore.—Red hæmatite having a perfect metallic lustre (pp. 338,

Titaniferous Iron Ore.—Ferric titanate. (See TITANATES.)

(p. 340). It is formed by heating iron or its lower oxides and hydrates in contact with the air.

Ferric oxide may be obtained in small crystals by decomposing ferric chloride with lime at a red heat (Daubré, Compt. rend. xlix. 143); in micaceous laminæ by heating the amorphous oxide with borax, and treating the resulting mass with hydrochloric acid (Hauer, Wien. Akad. Ber. xiii. 456), or by melting the amorphous oxide with chloride of calcium (Kuhlmann, Compt. rend. lii. 1283). Rhombohedral or laminar crystals of ferric oxide are likewise obtained by igniting the amorphous oxide in a slow current of hydrochloric acid gas. (Deville, Compt. rend. lii. 1264.)

When equal parts of ferrous sulphate (green vitriol) and common salt are heated to redness, and the product exhausted by washing, ferric oxide remains in red-brown shining scales. When pulverulent ferric oxide is ignited with sal-ammoniac, part of it becomes crystalline, while another portion volatilises as ferric chloride.

Ferric oxide is obtained in the amorphous state by igniting ferrous sulphate with $\frac{1}{12}$ pt. of saltpetre, and lixiviating the product; by dissolving iron in nitric acid, evaporating, and heating the resulting nitrate to redness; also by deflagrating iron filings with saltpetre. In the distillation of fuming sulphuric acid from green vitriol, a residue of impure ferric oxide is obtained, formerly known as *Caput mortuum vitrioli*. Amorphous ferric oxide is usually prepared for pharmaceutical use by igniting ferric hydrate or ferrous carbonate in contact with the air; the preparation thus obtained is called *Crocus Martis adstringens* or *Ferrum oxydatum rubrum*. Very pure ferric oxide may be prepared by heating ferrous oxalate in contact with the air; the salt then takes fire and is completely converted, without further heating, into ferric oxide. (A. Vogel.)

Ferric oxide prepared by either of the latter methods, is amorphous, and has a brown-red, red, or nearly black colour, according to the particular mode of preparation adopted. It is very hygroscopic, not magnetic, very hard, and is therefore used as a grinding and polishing material. The specific gravity of the artificially prepared oxide is 5·04 to 5·17 (H. Rose, Pogg. Ann. lxxiv. 440); that of red hæmatite and specular iron ore, from 4·5 to 5·3; of some columnar varieties as low as 4·2; that of martite from Peru, 3·80; from Puy de Dome, 4·65; from Brazil, 4·80 (Breithaupt); from Monroe, New York, 5·33 (Hunt). Hardness of hæmatite and specular iron ore = 5·5 to 6·5; of martite = 6. The cubic expansion of ferric oxide = 0·00004 for 1° C. (Kopp). Ferric oxide is not volatile, but at a full white heat it gives off oxygen, and is partially converted into ferroso-ferric oxide, which is attracted by the magnet.

Ferric oxide is reduced to the metallic state by *hydrogen gas*, at a heat even below redness, and completely at red heat by *charcoal* or *carbonic oxide*, also by *ammonia gas*. When ignited with *sulphur*, it yields sulphurous anhydride and a sulphide of iron. It easily gives up its oxygen when ignited with *combustible bodies*, but takes it up again when heated in contact with the air: hence it facilitates the combustion of organic bodies, and may be used for incinerating them (Gräger, Ann. Ch. Pharm. cxi. 124). Even at ordinary temperatures, it frequently acts as an oxidising agent in contact with organic matter, and is thereby reduced to magnetic oxide, or even to ferrous oxide, and then, by taking up carbonic acid, converted into spathic iron; the reduced oxide, if in contact with moisture, is frequently also reconverted into ferric hydrate (limonite or brown hæmatite) by atmospheric oxidation. The oxide is also sometimes further reduced by the action of *sulphydric acid*, and converted into pyrites: hence magnetite, limonite, and pyrites often occur as pseudomorphs after red hæmatite. According to Kuhlmann (Compt. rend. lii. 1169), it easily converts *sulphide of calcium* into gypsum at the expense of atmospheric oxygen; the oxysulphide of calcium of the soda-residues mixed with an equal weight of ferric oxide (the residue of the burning of pyrites), forms a very useful cement, which hardens quickly in contact with the air.

Ferric oxide dissolves in *acids*, but less easily in proportion as it has been more strongly ignited: the best solvent for it is strong boiling hydrochloric acid. The solution is facilitated by the addition of zinc or stannous chloride, the oxide then dissolving as ferrous chloride.

Ferric oxide, on account of its hardness, is much used as a grinding and polishing material. A very hard compact kind of red hæmatite, called bloodstone, forms, when well polished, the best material for producing a high lustre on coat-buttons, and on the gilding of porcelain. Ferric oxide in the pulverulent state is used for polishing gold, silver, and other metals, for polishing and sharpening cutting instruments, and for grinding and polishing glass for mirrors and lenses. According to Vogel (Dingl. pol. J. cxxxii. 275), the oxide obtained by the combustion of ferrous oxalate (p. 393) is peculiarly adapted for these purposes. That which is prepared by igniting green vitriol in crucibles is also much used, the least calcined portions, which are of a scarlet colour, forming *jeweller's rouge* for polishing gold or silver, and the more calcined portions, which are bluish or purplish, forming the *crocus* which

teel. Lord Rosse prepares ferric oxide for polish-, by precipitating a pure dilute solution of ferrous the washed precipitate in a screw-press till nearly h appears dull red in the dark. (See *Ure's Dictionary*

olouring material for glass and porcelain, especially red, or when more strongly heated, an orange-yellow depending essentially on the mode of treatment; Mag. [4] xxxv. 439), ferric oxide may be made to he spectrum, according to the degree of heat applied.

Ferrichydrate, occurs abundantly in nature, either e iron ore (ii. 940), or in stellate groups of needles more frequently in stalactitic, botryoïdal or mammil-ubfibrous structure; also massive and occasionally r limonite; also mixed with clay, as brown or 338, 339). It is the colouring principle of many of mineral waters, of yellow sandstone, Turkish precipitation of ferric salts with alkalis or alkaline s are precipitated in like manner, and the precipitate rusting of iron, which takes place when the metal is rated by contact with small quantities of acids, and lly ammoniacal salts and urine.

epared by precipitating a moderately dilute solution mmonia (with a smaller quantity, a basic salt would er, to retain small quantities of ammonia, to remove imes with water, then dried, and washed completely his precipitate formed in the cold (the *Ferrum oxi-eias*) has the composition $Fe^2O^3.2H^2O$, according to Lefort (J. pr. Chem. liv. 305); $Fe^2O^3.3H^2O$, accord-1853, p. 367); or $2Fe^2O^3.3H^2O$, according to Péan s. [3] xlvi. 47), the proportion of water doubtless dilution, the mode of precipitation, and the tem-been exposed in drying. The hydrate precipitated (Lefort; Schaffner, Ann. Ch. Pharm. li. 117.) of various composition. Göthite is $Fe^2O^3.H^2O$; lerite, $Fe^2O^3.2H^2O$; and a variety of bog iron ore wgorod in Russia, consists, according to Hermann $Fe^2O^3.3H^2O$.

w to dark brown colour, and is sometimes a loose friable mass, according to the mode of preparation. asily soluble in acids, but its power of uniting with frequently even by prolonged immersion in liquids. tion of ferric hydrate is produced by boiling the H^2O (precipitated from the chloride by ammonia), . The colour then changes from ochre-yellow to ered is scarcely acted upon by strong boiling nitric ochloric acid. In acetic acid, or dilute nitric or rming a red liquid, which is clear by transmitted, precipitated by the smallest quantity of an alkali-n of strong nitric or hydrochloric acid, yields a red lves on diluting the liquid with water. The modi-an blue with ferrocyanide of potassium and acetic $O^3.H^2O$. This insoluble hydrate is likewise preci-inary hydrate in acetic acid is rapidly boiled. The ime at 100° C. in a close vessel, becomes light in lue with ferrocyanide of potassium, or exhibits any a sulphocyanate; strong hydrochloric or nitric acid, phuric acid, throws down all the ferric oxide in the éan de Saint-Gilles, Ann. Ch. Phys. [3] xlvi. 47.) its water between 80° and 100°, and the whole at a ydrated by heating it to 160°—200°, with a satu-n or chloride of sodium. (Senarmont.)

part of its oxygen to oxidable bodies, and is easily nnous chloride, &c. In contact with putrefying ith the air, it forms ferroso-ferric compounds, or as access to it, it quickly recovers the oxygen which substance, and can then again exert an oxidising

Digitized by Google

action, thus acting as a carrier of oxygen from the air to the organic body: hence it accelerates the oxidation of woody fibre in the soil. (Kuhlmann, J. pr. Chem. lxxxi. 110.)

Ferric hydrate is rarely used alone in medicine; but in the recently precipitated state, it acts as an antidote to arsenic, as, when given in sufficient quantity, it forms a highly basic ferric arsenite, very difficultly decomposible by water.

Ferric hydrate unites with colouring matters, and easily fixes itself on many organic bodies, especially on tissues: hence its use as a mordant, and the formation of iron-mould on linen, cotton, &c. Such spots may be removed by oxalic acid, or acid oxalate of potassium, the action being greatly accelerated by contact with metallic tin.

Ferric salts.—In these salts, the iron may be regarded as trivalent, or the group Fe^2 as sexvalent, *e.g.* the chloride, Fe^2Cl^6; the nitrate, $Fe^2(NO^3)^6$; the sulphate, $Fe^2(SO^4)^3$. (The oxygen-salts may, of course, be regarded as compounds of ferric oxide with anhydrous acids, *e.g.* the nitrate, $Fe^2O^3.3N^2O^5$, the sulphate, $Fe^2O^3.3SO^3$.) Accordingly, it requires three molecules of a monobasic acid, such as nitric acid, to form a normal salt with one molecule of ferric oxide.

The normal ferric salts are for the most part soluble in water, and difficult to crystallise; some of them are deliquescent. They are mostly analogous in composition to the salts of aluminium, and frequently isomorphous with them; this correspondence of form and composition is most conspicuous in the alums; thus ferrico-potassic sulphate, $FeK(SO^4)^2.12H^2O$, is isomorphous with common alum, $AlK(SO^4)^2.12H^2O$.

Soluble ferric salts are obtained by dissolving ferric oxide or its hydrates in aqueous acids, or by oxidising ferrous salts with nitric acid, adding the quantity of acid required to form a normal ferric salt; *e.g.*:

$$2FeSO^4 + O + H^2SO^4 = Fe^2(SO^4)^3 + H^2O.$$

The insoluble salts are obtained by double decomposition.

Ferric salts are white in the anhydrous, yellow or yellowish-red in the hydrated state. The solutions have also, for the most part, a yellowish-red colour, especially when heated; the solutions of the nitrate and fluoride, however, are colourless; that of the chloride is brown-red, and those of the acetate, meconate, and sulphocyanate are blood-red.

The presence of free hydrochloric acid in a solution of ferric chloride changes the colour of the solution to orange yellow; this coloration, like that of other acid solutions of ferric salts (*e.g.* ferric sulphocyanate), is completely destroyed by addition of a sufficient quantity of phosphate of sodium; on the other hand, the colouring power of ferric chloride, in presence of an excess of strong hydrochloric acid, is very great, the bright yellow colour of commercial hydrochloric acid, for instance, being caused by a quantity of ferric chloride too small to impart a perceptible colour to the liquid when somewhat diluted with water.

Ferric oxide has a great tendency to form basic salts, which may be regarded as compounds of the normal salts with excess of ferric oxide: thus, besides the triacid or normal sulphate,

$$Fe^2O^3.3SO^4 = \ddot{Fe}^2(SO^4)^3 = \left.\begin{matrix}(S\ddot{O}^2)^3\\ \ddot{Fe}^2\end{matrix}\right\} O^6,$$

there are several basic sulphates, viz.

Sexbasic, $6Fe^2O^3.SO^3 = \left.\begin{matrix}S\ddot{O}^2\\ \dddot{Fe}^{12}\end{matrix}\right\} O^{19}$ or $17Fe^2O^3.Fe^2(SO^4)^3$

Quadribasic, $4Fe^2O^3.SO^3 = \left.\begin{matrix}S\ddot{O}^2\\ \ddot{Fe}^8\end{matrix}\right\} O^{13}$ or $11Fe^2O^3.Fe^2(SO^4)^3$

Tribasic, $3Fe^2O^3.SO^2 = \left.\begin{matrix}S\ddot{O}^2\\ \dddot{Fe}^6\end{matrix}\right\} O^{10}$ or $8Fe^2O^3.Fe^2(SO^4)^3$

Dibasic, $2Fe^2O^3.SO^3 = \left.\begin{matrix}S\ddot{O}^2\\ \dddot{Fe}^4\end{matrix}\right\} O^7$ or $5Fe^2O^3.Fe^2(SO^4)^3$

Monobasic, $Fe^2O^3.SO^3 = \left.\begin{matrix}S\ddot{O}^2\\ \ddot{Fe}^2\end{matrix}\right\} O^4$ or $2Fe^2O^3.Fe^2(SO^4)^3$

Sesquiacid, $2Fe^2O^3.3SO^3 = \left.\begin{matrix}(S\ddot{O}^2)^3\\ \dddot{Fe}^4\end{matrix}\right\} O^9$ or $2Fe^2O^3.2[Fe^2(SO^4)^3]$

Diacid, $Fe^2O^3.2SO^3 = \left.\begin{matrix}(S\ddot{O}^2)^2\\ \ddot{Fe}^2\end{matrix}\right\} O^5$ or $Fe^2O^3.2[Fe^2(SO^4)^3]$

γ. Crystallised ferrous carbonate, ignited in close vessels, yields ferroso-ferri consisting, according to Krämer, of $FeO.Fe^2O^3$; according to Döberei $3FeO.Fe^2O^3$; according to Glasson, of $4FeO.Fe^2O^3$, the composition of the being doubtless influenced by the rapidity of the heating.

δ. The old pharmaceutical preparation called *Æthiops martialis*, is a ferros oxide, or mixture of ferrous and ferric oxides in various proportions, obtai oxidising iron in a current of aqueous vapour, or by partially reducing ferric ox ignition with iron filings, or with a quantity of oil just sufficient to make it moist powder; the preparation obtained by this last method always contains c

Ferroso-ferric oxide is easily reduced to the metallic state by ignition with hy charcoal, carbonic oxide, or ammonia-gas. When ignited in the air, it is co into ferric oxide.

Ferroso-ferric Hydrates.—These are compounds of various comp obtained by the partial oxidation of ferrous, or reduction of ferric hydrate, cipitating mixtures of ferrous and ferric salts with alkalis, and by the oxidation in contact with air and water.

α. *Dingy-green Hydrate.*—By exposing white ferrous hydrate to the air for time—or by precipitating a mixture of a ferrous salt and a small quantity of fer with potash or ammonia—a dingy-green hydrate of ferroso-ferric oxide is ob which, on further exposure to the air, is quickly converted into rusty-brown hydrate.

β. *Black Hydrate.*—1. This hydrate, which has nearly the composition $FeO + xH^2O$, is precipitated from a solution of magnetic oxide in hydrochloric a from a mixture of equivalent proportions of ferrous and ferric salts, on the a of potash or ammonia. The yellow solution of magnetic oxide in hydrochlori yields, with ammonia, a brownish-black precipitate, which is magnetic even w the liquid, so that it collects round a magnet dipped into that liquid. It r washed on the filter without becoming more highly oxidised (Liebig and W Pogg. Ann. xxi. 583).—2. The same precipitate is obtained by mixing ferrico-an sulphate with ferrous sulphate, in such proportion that the ferric oxide present mixture may contain three times as much oxygen as the ferrous oxide, and p tating with ammonia (Abich, Pogg. Ann. xxiii. 354).—3. Two equal porti ferrous sulphate are taken; the first is dissolved in water acidulated with sul acid, and oxidated at a boiling heat by the addition of nitric acid in small porti a time. The other portion is dissolved in water freed from air by boiling. Th solutions are then mixed; the mixture, while still hot, precipitated by ammonia at once in excess; and the liquid, together with the brown-black precipitate, hea so e minutes to the boiling point. The precipitated ferroso-ferric oxide is th lected on a filter and washed—during which process it undergoes further oxida and then dried at a gentle heat (Wöhler, Ann. Ch. Pharm. xxii. 56). This should yield $2FeO.Fe^2O^3$; but even if a greater quantity of ferric oxide is n duced by the nitric acid still remaining, or by contact with the air, the propor that oxide is sure to be increased by decomposition of water.—4. Böttger (*Be* ii. 12) precipitates ferrous sulphate free from ferric oxide by the addition of carbo sodium; washes the precipitate several times by decantation; and then boils tolerably concentrated caustic potash. This process yields a velvet-black p much less liable to absorb an additional quantity of oxygen than that which ha precipitated by ammonia.—5. Noel (J. Pharm. [3] i. 62) precipitates ferrous su with carbonate of sodium, washes the ferrous carbonate by decantation, leave drain upon linen, and then heats it in a cast-iron vessel, with constant stirring, is dry. It is thereby converted into a velvet-black powder. Soubeiran obtain this process a precipitate which was not perfectly black, and when treated with chloric acid, evolved carbonic anhydride.—6. Preuss introduces 4 pts. of pulv iron and 5 pts. of ferric oxide into a flask, together with a two or threefold quan water, and boils the liquid gently for some time. The mixture gives off fetid hy gas, and turns dark brown at first, but afterwards black. When the evolution ceases, and the resulting black powder settles down readily, it is separated by tion from the excess of iron; thrown on a filter of grey porous paper; and the after the water has drained off, is wrapped up in a large quantity of paper, and q dried in hot air. The black, very loose powder dissolves in acids without evolu gas, and the solution yields a black precipitate on the addition of an alkali. Th cipitate must not be dried by heat, because in that case it would turn brow higher oxidation. (Wöhler, Ann. Pharm. xxviii. 92.)

The black hydrate of ferroso-ferric oxide exhibits, after drying, the appear brown black, brittle, strongly magnetic lumps, having a conchoïdal fracture, and ing a dark-brown powder. It contains about 7 per cent. of water, which it gi when heated in a retort, leaving black anhydrous ferroso-ferric oxide. When

greyish-yellow, easily pulverisable compound, having a specific gravity of 6 the composition of ferric selenide, Fe^2Se^3.

IRON, SULPHIDES OF. Iron and sulphur unite directly with one under various circumstances, and in several different proportions. Besides t sulphides containing less than 1 at. sulphur to 1 at. iron, there is a *protosul ferrous sulphide*, FeS; a *sesquisulphide* or *ferric sulphide*, Fe^2S^3; a *disulphid* and a compound called the *magnetic* sulphide, intermediate in composition bet proto- and sesqui-sulphides. Metallic iron heated with excess of sulphur, yi or other of the four last-mentioned compounds, according to the heat appl degree of sulphuration being less as the temperature is higher. (Rammel Pogg. Ann. cxxi. 337.)

An **octoferric sulphide**, Fe^8S, is formed by passing hydrogen-gas over dibasic ferric sulphate (p. 396). It is a blackish-grey magnetic powder, whic treated with dilute acids, yields a mixture of 7 vols. hydrogen-gas and 1 phydric acid.

A **hemisulphide**, Fe^2S, is produced by heating anhydrous ferrous sulp hydrogen gas, half of the sulphur being then given off as sulphurous anhydrid a dark grey, coherent, magnetic powder, which dissolves easily in dilute acids off equal volumes of hydrogen and sulphydric acid. When ignited in sulphyd gas, it takes up sulphur and is converted into the protosulphide. It occurs, cc with other metallic sulphides, in many furnace-products obtained in the sme lead and copper ores.

Protosulphide, or Ferrous sulphide, FeS. This compound occurs i specimens of meteoric iron, sometimes imbedded in small yellow-brown masses times as a grey powder possessing metallic lustre. (Berzelius; Rammel Pogg. Ann. cxxi. 363.)

It has not been found in the free state as a terrestrial mineral, but exists in nation with sulphide of nickel, and mixed with copper-pyrites, in a massive, coloured mineral, with octahedral cleavage and specific gravity = 4·60, fron hammer, in Norway. This mineral, after deducting 5·14 per cent. of copper contains 36·7 per cent. sulphur, 41·1 iron, and 22·2 nickel, agreeing approx with the formula $2FeS.Ni^2S$. (Rammelsberg, *loc. cit.*)

Ferrous sulphide is produced: 1. By the direct combination of sulphur an either at a red heat, or at lower temperatures in presence of water.—α. Heat wire introduced into sulphur-vapour burns brightly, and forms ferrous sulp β. When iron filings are gradually heated in a covered crucible with about tw their weight of sulphur, the mass, when heated to about the temperature of l ness, begins to glow, and combination rapidly takes place, with vivid com throughout the entire mass.—γ. Sulphur pressed against a red-hot iron bar, pe it, and forms ferrous sulphide, which runs off in drops, and may be quenched in δ. Ferrous sulphide may also be obtained in the wet way by moistening a mix 28 pts. iron filings and 16 pts. sulphur, and applying a gentle heat; combinatio takes place, attended with considerable rise of temperature. When a consi quantity of mixture of 2 pts. sulphur and 3 pts. iron-filings is made into a pas water, and covered with earth, the mass after a while becomes red-hot, and giv large quantity of steam, which throws up the earth with violence, producing th of an artificial volcano.

2. By igniting ferric oxide or scale-oxide of iron with sulphur.—3. By heati pyrites, ferric sulphide, or magnetic pyrites, either alone to a bright red heat, c iron filings, or in an atmosphere of hydrogen.—4. By reducing ferrous sulph bright red heat in a crucible lined with charcoal. Ferrous sulphate is also red sulphide in the wet way by contact with decomposing organic matter.—5. By tating ferrous salts with alkaline sulphides.

Ferrous sulphide prepared in the dry way is a dense yellow mass with lustre, or sometimes a black porous mass. It is sometimes magnetic, but accor Berzelius, only when it contains a portion of one of the higher sulphides. It d alter sensibly by exposure to the air at ordinary temperatures, and is not deco by ignition, even to whiteness, in close vessels; but when gently heated in the a partly converted into ferrous sulphate; while at a stronger heat, sulphurous anhy evolved, and ferric oxide remains behind. With *nitric acid* it evolves nitro ferric oxide and sulphuric acid being formed, and sulphur separated. It disso dilute *sulphuric* or *hydrochloric acid*, with evolution of pure sulphydric acid g however, it is mixed with metallic iron, which is generally the case with the p phide obtained by igniting iron filings with sulphur, it gives off a mixture of sul acid and free hydrogen. *Aqueous vapour* passed over red-hot proto-sulphide converts it, with evolution of much hydrogen and sulphydric acid gas, into a bl

gnetic mass. The water forms with the sulphide of iron, sulphydric acid and ide, which, by further decomposition of water, yields hydrogen gas and ric oxide; but a portion of the sulphur remains, even after three hours' Regnault, Ann. Ch. Phys. [2] lxii. 379). *Chlorine gas* does not decompose ide of iron; but that compound, when heated in the gas, yields chloride of d sublimed ferric chloride (H. Rose, Pogg. Ann. xlii. 540). Protosulphide ated to low redness with once or twice its weight of *carbonate of sodium* or fuses into a black, crystalline, highly magnetic mass, from which water ulphide of sodium or potassium, with a trace of sulphuric acid. *Baryta* and re in the same manner, only that the viscidity of the slag prevents the iron ng into a mass (Berthier, Ann. Ch. Phys. [2] xxxi. 170). When proto- f iron is fused with 30 times its weight of *protoxide of lead*, the whole of r is given off in the form of sulphurous anhydride, metallic lead is separated, d mixture of protoxide of iron and protoxide of lead is produced.

sulphide prepared in the wet way is a black amorphous substance, perhaps water; in the finely divided state, it has a dark green colour. In the moist xidises quickly on exposure to the air, being converted, first into ferrous hen quickly into yellow-brown basic ferric sulphate. It exhibits the same as the protosulphide prepared in the dry way, but is much more easily d, and dissolves much more quickly in acids, with violent evolution of acid gas.

ck mud at the bottom of drains, cess-pools, ponds and morasses, owes its sulphide of iron, probably formed by the putrefaction of organic matters in th ferric oxide contained in the soil.

sulphide or **Ferric Sulphide.** Fe^2S^3.—This compound is probably ient of copper pyrites, $Cu^2S.Fe^2S^3$ (ii. 77), and of magnetic pyrites). It is produced by heating iron to moderate redness, or ferric oxide to s with excess of sulphur: in the latter case, however, the product is mixed oxide, unless the process is several times repeated (Rammelsberg, Pogg. 339). According to Berzelius, it may also be obtained by the action of acid on ferric oxide at 100°, or on ferric hydrate at ordinary temperatures, ping a neutral solution of ferric sulphate into excess of sulphydrate of am- According to Rammelsberg, however, the product obtained by heating ferric lphydric acid gas to a temperature short of redness, is an oxysulphide con- . ferric oxide to 3 at. ferric sulphide; after stronger heating, the product contains oxide, but in place of it a certain quantity of ferrous sulphide; and if the ised to bright redness, there remains at last a sulphide of iron free from d having the composition of magnetic pyrites.

ulphide dried out of contact with air, is a yellow-grey, non-magnetic powder, ted to redness in close vessels, it gives off sulphur and leaves magnetic In the moist state it oxidises very quickly in contact with the air, especially ared by precipitation of ferric salts. Acids decompose it, with formation of t, evolution of sulphydric acid, and precipitation of sulphur.

o-ferric or **Magnetic Sulphide.**—This sulphide occurs native as mag- es, and is formed by heating iron with a slight excess of sulphur till the ; also by heating the disulphide to redness in a covered crucible. As thus it has a brownish-yellow to speiss-yellow colour; is attracted by the d sometimes itself magnetic. It does not lose weight when simply ignited ssels, but when heated in *hydrogen gas*, it yields sulphydric acid and the ide. Dilute *acids* dissolve it, with separation of sulphur and evolution of acid. Boiling *potash-ley* is said to remove a portion of the sulphur, leaving lphide.

tic pyrites or Pyrrhotin occurs in crystals belonging to the hexagonal l generally tabular, exhibiting the combinations oP . P, oP . ∞P, oP . ∞P . P, 239, 240 (ii. 139) and others. Ratio of principal to secondary axes = 1 : 1·741. P in the terminal edges of the pyramids = 126° 49′; in the lateral edges . Cleavage tolerably distinct parallel to oP, indistinct parallel to ∞P. More massive and amorphous, with granular structure. Hardness = 3·5 to 4·5. avity, 4·51 to 4·64 (Rammelsberg). Lustre metallic. Colour between low and copper-red. Streak dark greyish-black. Fracture small subcon- Brittle. Slightly attracted by the magnet. Tarnishes quickly. Before the t gives off sulphurous anhydride, and on charcoal in the outer flame, is into ferric oxide; in the inner flame it melts and continues to glow after the s removed. The mass, after cooling, is magnetic and has a metallic crystal- ure, with a yellowish colour on the fractured surface.

These analyses may be represented by the formula, $M^5S^6 = 3MS.M^2$ $M^6S^7 = 4MS.M^2S^3$, where M stands for Fe (56) and Ni (58·9), each metal being in both degrees of sulphuration. (Rammelsberg.)

Disulphide of Iron. FeS^2.—This compound occurs abundantly in in two distinct forms, viz. as *Yellow Iron pyrites*, *Cubic pyrites* or *Mundic* crystallises in monometric forms, and *White Iron pyrites*, *Marcasite*, *Radiated Spear pyrites*, *Hepatic pyrites*, or *Cellular pyrites*, which crystallises in t forms. Cubic pyrites occurs abundantly in rocks of all ages, from the crystalline to the most recent alluvial deposits, and has been found in small i crystals in the Vesuvian lavas. Marcasite occurs also in rocks of various age found in granite, gneiss, and mica slate, and abundantly in the plastic clay of th coal formation near Carlsbad in Bohemia. The peculiar circumstances whic mine the formation of one or other of these varieties are not known; neither ha found possible to convert the one into the other. Iron pyrites is often form iron salts, in presence of putrefying organic matters, such as straw, wood, sulphide of iron thus produced retaining the form of the organic substance.

Yellow iron pyrites occurs in a great variety of monometric forms, th nant forms being the cube, the octahedron, the trapezohedron 202 (*fig.* 180, the pentagonal dodecahedrons $\frac{2O\infty}{2}$ (*fig.* 192), and $\frac{3O\infty}{2}$, the hexakistetrahedr and $\frac{4O2}{2}$ (hemihedral forms of the hexakis-octahedron, ii. 127), these forms o either alone or in combinations, such as *figs.* 194, 195, 196, 211, and numerou Twin-crystals are also found resulting from the intersection of two pentagonal hedrons. Cleavage cubic and octahedral, more or less distinct; the cubic a hedral faces are often striated. It likewise occurs radiated, subfibrous, and r often reniform or globular, with a crystalline surface. Hardness = 6 to 6·5. gravity 4·083 to 5·031 (Dana); 5·0 to 5·2 (Rammelsberg). Lustre splendent; colour, bronze-yellow, nearly uniform. Streak, brownish black, Fracture conchoïdal, uneven. Brittle, strikes fire with steel. [For analy p. 343.]

White iron pyrites or marcasite forms trimetric crystals, in which *a* : 0·7454 : 1 : 1·1548. Angle $\infty P : \infty P = 73° 24'$; $\breve{P}\infty : \breve{P}\infty$ in the basal p

= 98° 13'. The crystals are pyramidal and prismatic combinations, the faces
g frequently predominant in the latter. Cleavage tolerably distinct, parallel
It occurs also in globular, reniform, and other imitative shapes; often massive,
r, or granular. Hardness = 6 to 6·5. Specific gravity = 4·678 to 4·847
; 4·85 to 4·88 (Rammelsberg). Lustre metallic. Colour, pale bronze-
ometimes inclining to green or grey. Streak, greyish-black or brown-black.
uneven. Brittle.

hide of iron is produced artificially: 1. By heating iron with excess of
to a temperature below redness (Rammelsberg, Pogg. Ann. cxxi. 339).—
posing ferric oxide or hydrate, ferroso-ferric hydrate, or ferrous carbonate, at a
ve 100°, but not amounting to redness, to a stream of sulphydric acid gas,
s the mass continues to increase in weight. At first the action is so strong,
eous vapour, sulphurous anhydride, and hydrogen are evolved, and lower sul-
f iron are formed; but these afterwards take up more sulphur, and liberate
drogen gas. The sulphide of iron thus produced retains the crystalline form
xide used in its preparation, with the same lustre on the faces, and the same
s of cleavage (Berzelius).—3. The lower sulphides of iron may be brought
he highest degree of sulphuration, by heating them in like manner in sul-
acid gas (Berzelius).—4. An intimate mixture of 2 pts. protosulphide of
1 pt. sulphur, heated in a retort to a temperature short of redness, leaves
le of iron as a bulky, dark yellow, non-magnetic, metallic powder, not attacked
ochloric acid (Berzelius).—5. When an intimate mixture of ferric oxide,
and sal-ammoniac is heated to a temperature a little above that at which the
oniac sublimes, the residue is found to contain small, brass-yellow octahedrons
es, which may be separated from the rest of the powder by levigation (Wöhler,
nn. xxxvii. 288).—6. When sal-ammoniac containing sulphate of ammonium is
at a dull red heat in iron vessels coated with clay, the clay covering becomes
ated with chloride of iron, and cubes and octahedrons of iron pyrites form upon
ce (Löwe, *J. pr. Chem.* vi. 98).—7. The compound may also be prepared in
way by mixing solutions of alkaline persulphides with ferrous chloride at
ferrous sulphate at 165°. (Senarmont, Ann. Ch. Phys. [3] xxx. 129.)

ially prepared disulphide of iron differs in character according to the mode of
ion adopted, being either a bulky dark yellow powder (Berzelius), or crys-
in small brass-yellow cubes and octahedrons (Wöhler), or a black powder
mont). It is not magnetic, is not attacked by dilute acids, but is decomposed
ng with strong hydrochloric acid, with evolution of sulphydric acid, and sepa-
sulphur, and is oxidised when heated with strong nitric acid or with nitro
acid.

w iron pyrites in its compact forms, and the denser varieties of the artificial
le, do not alter by exposure to the air, and even that which is prepared in the
oxidises but slowly in the air, and only when moist; but white iron pyrites
very rapidly, and the yellow variety in the finely divided state oxidises even
ary temperatures, with sensible evolution of heat, as in the roasting of alum-
nd the spontaneous heating of coal or lignite containing pyrites, which some-
ecomes intense enough to set fire to inflammable substances, and gives rise to
taneous combustion of coal-mines. The products of this spontaneous oxidation
ong as the temperature remains moderate, sulphuric acid and ferrous sulphate,
eparates partly in crystals, partly as an efflorescence on the surface, but is for
part dissolved out by the water which permeates the mass (see SULPHATES);
higher temperatures, sulphurous anhydride is evolved, and ferric oxide is
h only a small quantity of sulphuric acid. This reaction renders iron pyrites
e for the manufacture of sulphuric acid (*q. v.*). When ignited with charcoal,
sulphide of carbon. Mixed with 10 per cent. charcoal, and exposed to the
f a mixture of superheated steam and atmospheric air, it is completely desul-
, giving off sulphur, sulphydric acid, and sulphurous anhydride, together with
anhydride and carbonic oxide, while the iron remains, according to cir-
ces, either in the metallic state or as ferric oxide. (Brunfaut, Journ. des
1861, No. 5.)

MIC ACID. $C^{16}H^{12}N^2O^4$. *Imasatic acid, Rubindenic acid.* (Laurent,
. Phys. [3] iii. 490.)—This acid is produced by the action of warm ammonia
n; but the best mode of preparing it is to dissolve isatin to saturation in

Digitized by Google

aqueous potash; evaporate the solution to dryness; dissolve in alcohol; mix the solution with a very concentrated solution of sulphate of ammonium (in the proportion of rather more than 1 at. of that salt to 1 at. isatin); filter to separate sulphate of potassium; evaporate the filtered liquid to dryness, whereby the isatate of ammonium is converted into isamate; then boil with alcohol; filter to separate isamide and sulphate of ammonium; and neutralise the filtrate with hydrochloric acid, taking care to avoid an excess. Isamic acid then separates in crystals on cooling. If a small quantity of isatin should likewise separate, in consequence of too much hydrochloric acid having been added, or of too great a heat having been applied, or of the solution of isatate of ammonium not having been sufficiently evaporated, the crystals must be treated with weak ammonia, which dissolves the isamic acid and leaves the isatin.

Isamic acid crystallises in splendid, shining, rhombic laminæ, of the colour of red iodide of mercury. By spontaneous evaporation of the solution, ruby-coloured hexagonal tables are formed, with angles of about 110°. It dissolves sparingly in boiling water, forming a yellow solution, easily soluble in hot alcohol, somewhat less in ether.

Isamic acid dissolves with fine violet colour in hydrochloric acid. By boiling with dilute acids, it is converted into ammonia and isatin. Bromine attacks it violently, forming *indelibrome*, $C^{16}H^{5}Br^{4}N^{3}O^{3}$, a yellow substance insoluble in water.

Isamate of ammonium, $C^{16}H^{12}(NH^{4})N^{3}O^{4}$, crystallises in small needles or very acute microscopic rhombs. When somewhat strongly heated, it gives off water, and is converted into isamide. Its solution does not precipitate the salts of barium, calcium, or magnesium. It forms a yellow precipitate with *acetate of lead*, red with *mercuric chloride*, yellow with *nitrate of silver*.

Isamate of potassium may be boiled without decomposing.

Dichlorisamic acid, $C^{16}H^{11}Cl^{2}N^{3}O^{4}$.—Produced by adding hydrochloric acid to a solution of dichlorisamide in dilute potash, and crystallising the brick-red flocculent precipitate from alcohol. It forms bright red elongated hexagonal laminæ, derived from a rhombus of about 110°. It is more soluble than isamic acid in alcohol and ether, and forms yellow solutions. It is decomposed by distillation. Strong acids dissolve it, with violet colour, at ordinary temperatures; but at the boiling heat, they convert it into ammonia and chlorisatin.

Tetrachlorisamic acid, $C^{16}H^{9}Cl^{4}N^{3}O^{4}$.—Tetrachlorisamide is converted by boiling alcohol into tetrachlorisamate of ammonium; and on adding nitrate of silver to this salt, a flocculent precipitate is formed containing $C^{16}H^{8}AgCl^{4}N^{3}O^{4}$.

ISAMIDE. $C^{16}H^{14}N^{4}O^{3}$. *Amasatin.* (Laurent, Ann. Ch. Phys. [3] iii. 488.) Produced by heating isamate of ammonium till water is given off, and washing the residue with water. It is pulverulent, of a fine yellow colour, tasteless, inodorous, insoluble in water, nearly insoluble in ether, very sparingly soluble in alcohol, moderately soluble in boiling alcohol containing ammonia. Potash dissolves it with yellow colour, with elimination of ammonia; the solution contains isatin.

ISATAN. $C^{16}H^{12}N^{2}O^{3}$? (Laurent, J. pr. Chem. xxviii. 346.)—This body is sometimes produced when disulphisatyde is boiled with acid sulphite of ammonium, as a white precipitate, which dissolves when boiled with a large quantity of alcohol, and is deposited on cooling in crystals, which appear under the microscope, either as well-defined rectangles, or as pointed ovals, according to the side on which they are viewed. The compound, heated till it melts, turns brownish red, and yields a mixture of isatin and indin:

$$\underset{\text{Isatan.}}{3C^{16}H^{12}N^{2}O^{3}} = \underset{\text{Isatin.}}{2C^{8}H^{5}NO^{2}} + \underset{\text{Indin.}}{2C^{16}H^{12}N^{2}O^{2}} + H^{2}O.$$

It is decomposed by boiling nitric acid, with formation of a violet powder, similar to nitrindin. With alcoholic potash it forms a yellow solution, from which water precipitates hydrindin, and hydrochloric acid throws down isatin mixed with a resinous substance.

The composition of isatan is equal to that of 2 at. indigo-blue + 1 at. water ($2C^{8}H^{5}NO + H^{2}O$), and to that of isatyde *minus* 1 at. oxygen ($C^{16}H^{12}N^{2}O^{4} - O$).

ISATIC ACID. $C^{8}H^{7}NO^{3}$. (Laurent, Ann. Ch. Phys. [3] iii. 371.)—The potassium-salt of this acid is produced by the action of caustic potash upon isatin. The acid itself is not easily obtained in the free state.

The solution of the potassium-salt mixed with hydrochloric acid, deposits, after a while, crystals of isatin, which in fact differs from isatic acid, only by the elements of water:

$$\underset{\text{Isatic acid.}}{C^{8}H^{7}NO^{3}} = \underset{\text{Isatin}}{C^{8}H^{5}NO^{2}} + H^{2}O.$$

The composition of the isatates is represented by the formula $C^{8}H^{6}MNO^{3}$. The ammonium-salt appears to be capable of existing only in solution; for on evaporation to

nately crimson, these changes of colour arising from the crystallisation of the salt within the liquid. The *lead-salt* is a yellow precipitate. The *silver-salt* is a light yellow precipitate, which dissolves in a large quantity of boiling water, and crystallises on cooling in transparent yellowish needles, grouped in tufts. When heated in contact with the air, it melts to a brown mass, and yields a sublimate of dichlorisatin.

ISATILIM. $C^{24}H^{16}N^4O^5 = 3$ at. isatin + $NH^3 - H^2O$.—A substance stated by Laurent (J. pr. Chem. xxxv. 121) to be sometimes obtained when dry ammonia-gas is passed over isatin moistened with alcohol. Yellow non-crystalline flocks easily decomposed by potash. Its composition is rather doubtful.

ISATIMIDE. $C^{24}H^{17}N^5O^4$. (Laurent, *loc. cit.*)—Obtained by passing dry ammonia-gas over isatin moistened with alcohol, either ordinary or absolute. When absolute alcohol is used, *imesatin* (p. 246) first crystallises out in prisms with square or rectangular base; and the solution decanted therefrom deposits isatimide in the form of a yellow, shining, crystalline powder. It is insoluble in water, scarcely soluble in boiling alcohol or in ether, but dissolves easily in boiling alcohol, containing ammonia. Potash dissolves it with yellow colour and evolution of ammonia; the liquid contains isatin.

ISATIN. $C^8H^5NO^2$. (Laurent, Ann. Ch. Phys. [3] iii. 371.—Erdmann, J. pr. Chem. xxiv. 11.—A. W. Hofmann, Ann. Ch. Pharm. liii. 11.—Gm. xii. 51.—Gerh. iii. 534.)—This body, which was discovered simultaneously by Laurent and by Erdmann, in 1841, is produced by the action of nitric or chromic acid upon indigo:

$$\underset{\text{Indigo.}}{C^8H^5NO} + O = \underset{\text{Isatin.}}{C^8H^5NO^2}.$$

Preparation.—1 kilogramme of finely powdered, good commercial indigo is stirred up in a large dish to a thin paste with water; it is then placed over a moderate fire, and commercial nitric acid is gradually added (which causes a violent effervescence, without evolution of nitrous acid), until the blue colour has disappeared, for which, from 600 to 700 grms. of nitric acid are necessary. The solution is boiled with several quarts of water, and filtered at the boiling heat, as rapidly as possible; after 12 hours, the isatin separates in reddish crystalline nodules. The mother-liquor is boiled with the undissolved residue and filtered, the operation being two or three times repeated: the last mother-liquor still yields isatin on evaporation. The crystals are moistened with water containing a little ammonia, in order to remove a resinous matter; they are then washed with cold water, and finally recrystallised several times from boiling alcohol (100 pts. of indigo yield 18 pts. of isatin) (Laurent). When an excess of nitric acid is employed, nitrosalicylic acid is formed. After each addition of nitric acid, it is necessary to wait until the effervescence is over. If no effervescence takes place, in consequence of the indigo being mixed with too much water, and if the boiling is continued, whilst more and more nitric acid is added, a violent reaction suddenly ensues when the solution has reached a certain concentration, the mass overflowing the vessel even when it is very capacious: the residue generally contains nitrosalicylic acid (Hofmann).—2. Indigo is heated with chromic acid, properly diluted, until the whole nearly boils, when it is filtered hot; isatin then crystallises out on cooling, and is purified by repeated recrystallisation from water, and lastly from alcohol. If the chromic acid is so concentrated that it causes an evolution of carbonic anhydride, the solution deposits little or no isatin on cooling, but a small quantity by spontaneous evaporation or in vacuo; on evaporating the solution by heat, only sesquioxide of chromium and a brown powder separate (Erdmann). Laurent drops a dilute aqueous solution of chromic acid upon powdered indigo, and warms the mixture, the addition of chromic acid being discontinued as soon as the blue colour has disappeared, and the process continued as in (1). In order to purify crude isatin, which still contains resin, Hofmann dissolves it in potash, and carefully adds hydrochloric acid to the solution, as long as it forms a black or brown precipitate; when a portion on filtering is of a pure yellow colour, and gives a highly red precipitate with hydrochloric acid, the whole solution is filtered off, decomposed with hydrochloric acid, and the precipitate washed with a little water.

Properties.—Isatin crystallises in large, transparent, brownish-red prisms, or in smaller yellowish-red prisms, belonging to the trimetric system; the crystals are very brilliant, especially when obtained from an alcoholic solution. They exhibit the combination $\infty P . \infty\breve{P}\infty . \breve{P}\infty$; the faces $\infty\breve{P}\infty$ greatly predominating. Inclination of the faces $\infty P : \infty P = 133° 50'$ to $133° 55'$; $\breve{P}\infty : \breve{P}\infty = 127° 15'$ to $127° 30'$ (G. Rose, J. pr. Chem. xxiv. 11). Isatin is inodorous, and has a bitter taste. It melts when heated, and solidifies on cooling in a crystalline mass of needles; when heated above its melting point in contact with the air, the greater part volatilises, without decomposition, in yellow and very irritating vapours. It dissolves sparingly in cold, more freely in boiling *water*, forming a solution of a dark-reddish yellow colour. *Nitric*

potash converts it, at mean temperatures, into bromisatate of potassium. Distilled with hydrate of potassium, it yields bromophenylamine.

Dibromisatin. $C^8H^3Br^2NO^2$. (Erdmann, *loc. cit.*—Hofmann, *loc. cit.*—Laurent, Ann. Ch. Phys. [3] iii. 380.)—This body remains in the alcoholic mother-liquors obtained in preparing bromisatin, by the first of the methods above described, and may be separated by crystallisation; but a better way of preparing it is to digest isatin or bromisatin with bromine in sunshine, as long as hydrobromic acid continues to escape. It is purified by crystallisation from alcohol, from which it separates in shining orange-coloured trimetric prisms. When distilled with hydrate of potassium, it yields dibromophenylamine.

Dibromisatite of potassium, $C^8H^2KBr^2NO^2$, is obtained by gently heating a solution of dibromisatin in absolute alcohol, and pouring into it a hot solution of alcoholic potash. It crystallises in black scales, blue by transmitted light.

Chlorisatin. $C^8H^4ClNO^2$. (Erdmann, Ann. Ch. Pharm. xxiii. 129.—Laurent, Ann. Ch. Phys. [3] iii. 478.—Hofmann, Ann. Ch. Pharm. liii. 12.)—Produced: 1. By passing chlorine into tepid water, in which isatin is suspended.—2. By the action of chlorine on pulverised indigo suspended in water. A large quantity of a reddish yellow substance is thereby produced, consisting of a mixture of chlorisatin and dichlorisatin, which may be separated by solution in boiling alcohol, the chlorisatin separating out first. It is purified by repeated crystallisation from alcohol.

Chlorisatin crystallises in orange-coloured prisms, isomorphous with isatin. Observed combination, $\infty P \cdot \infty \breve{P}\infty \cdot \breve{P}\infty$. Inclination of the faces, $\infty P : \infty P = 131°$; $\breve{P}\infty : \breve{P}\infty = 134° 12'$ (G. Rose). It is inodorous, but has a bitter taste. Its dust irritates the organs of respiration and provokes sneezing. It is insoluble in cold water, but dissolves readily in boiling water and in alcohol. The solutions impart a disagreeable odour to the skin. Heated in contact with the air, it melts to a brown liquid, and gives off yellow vapours having the odour of burning indigo. At a high temperature, it partly sublimes and is partly carbonised.

Chlorisatin behaves with reagents like isatin. It dissolves in strong *sulphuric acid*, and separates on addition of water. With *nitric acid* it yields a resinous substance, oxalic acid, and a small quantity of an azotised body, which crystallises in yellow grains. *Sulphydric acid gas* passed into an alcoholic solution of chlorisatin, forms a white precipitate which increases on addition of water. Erdmann calls this precipitate sulphochlorisatin; according to Gerhardt, it is perhaps chlorinated tetrasulphisatyde, $C^{16}H^{10}Cl^2N^2S^4$ (analysis, 41·7 C, 2·37 H, and 31·09 S; calculation, 44·7 C, 2·33 H, 29·83 S).

Caustic *potash* communicates a deeper colour to chlorisatin, converting it into chlorisatite of potassium; on heating the liquid, the colour disappears, and the liquid contains chlorisatate of potassium.

Chlorisatite of argentammonium, $C^8H^3(NH^3Ag)ClNO^3$, is a crystalline precipitate, of the colour of wine-lees, obtained by pouring an ammoniacal solution of nitrate of silver into an alcoholic solution of chlorisatin mixed with ammonia.

Dichlorisatin, $C^8H^3Cl^2NO^2$, is obtained from the alcoholic mother-liquors, which have yielded chlorisatin, and is purified by recrystallisation from alcohol. It crystallises in small shining reddish-yellow needles, or shortened laminæ, fusible, partly volatile when heated in a close vessel, soluble in water and in alcohol.

Aqueous *potash* acts upon it in the same manner as upon chlorisatin. When dichlorisatin is thrown upon solid potash moistened with absolute alcohol, a red solution is formed, which after a short time, solidifies in a violet-black magma composed of dichlorisatite of potassium, the solution of which forms with nitrate of silver a precipitate having the colour of wine-lees.

Chlorine does not act upon chlorisatin or dichlorisatin in presence of water, but when either of these bodies is dissolved in hot alcohol of 80 per cent., and chlorine gas is passed through the liquid until nothing is formed but products of the decomposition of alcohol, a brownish yellow viscid mass is deposited at the bottom of the vessel, containing shining laminæ of *perchloroquinone* (chloranil). Water extracts sal-ammoniac from this mass, and alcohol dissolves chloride of ethyl, pentachloropicric acid, and a resinous mass which forms the largest portion of the product. The supernatant yellow solution contains products of the action of chlorine upon alcohol, and yields by distillation, a residue corresponding to the resinous substance, but not containing perchloroquinone. (Erdmann, Hofmann.)

ISATOSULPHURIC ACIDS. (G. and A. Schlieper, Ann. Ch. Pharm. cxxi. 1.)—Sulphindigotic acid, treated with oxidising agents, such as nitric acid or chromic acid, yields a monobasic acid containing the elements of isatin and sulphuric anhydride, viz. $C^8H^5NO^2.SO^3$; and the salts of this acid, treated with alkalis, yield a dibasic acid, containing the elements of isatin and sulphuric acid, viz. $C^8H^5NO^2.SO^4H^2$.

These salts are formed, as already observed, by the action of alkalis on the monobasic isatosulphates. All alkalis produce the change provided they are added in excess; if an insufficient quantity of alkali be added, a deep red, or sometimes dirty violet colouring is produced, which, though transient, is sufficient to indicate the formation of an intermediate compound. The transformation is likewise effected by alkaline carbonates.

Dibasic isatosulphuric acid has not been isolated; when separated from the solution of either of its salts, it is converted in a short time at ordinary temperatures, immediately when heated, into the monobasic acid.

The *diammonic salt* is produced by boiling isatosulphuric acid for some time with excess of ammonia, or by decomposing the dibarytic salt with sulphate of ammonium. The solution dries up, in vacuo over oil of vitriol, to a yellow gummy mass exhibiting but slight traces of crystallisation.

The *dibarytic salt*, $C^8H^5Ba''NSO^6.3H^2O$, is obtained by dissolving the monobarytic salt in boiling baryta-water, and removing the excess of baryta with carbonic acid. The slightly coloured solution yields, by evaporation or cooling, shining, lemon-yellow silky needles, more soluble than the monobasic salt in water, but insoluble in alcohol.

The *diplumbic salt*. $C^8H^5Pb''NSO^6.\frac{3}{2}H^2O$, is obtained by mixing a concentrated solution of the yellow potassium-salt with an excess of a concentrated solution of acetate of lead; it crystallises in slender, shining, dark yellow needles, which dissolve readily in water.

The *dipotassic salt*, $C^8H^5K^2N^2SO^6.H^2O$, obtained by decomposing the barium-salt with neutral sulphate of potassium, crystallises slowly, by spontaneous evaporation, in hard, shining, transparent, wax-yellow prisms, which dissolve readily in water, and give off their water of crystallisation between 140° and 150°.

The *diargentic acid*, $C^8H^5Ag^2NSO^6.\frac{3}{2}H^2O$, separates on mixing a solution of the potassium-salt with excess of nitrate of silver, in concentric groups of bulky needles, which, after drying, form a light spongy pale yellow mass. It is sparingly soluble in water, and does not give off its water of crystallisation till heated above 100°.

ISATOSULPHITES. (Laurent, Rev. scient. x. 289.—Gm. xiii. 56.—Gerh. iii. 544.)—Sulphurous anhydride does not act upon isatin alone; but in presence of potash or ammonia, peculiar salts are produced, containing the elements of isatate of ammonium or potassium, together with sulphurous anhydride. The acid corresponding to these salts has not been isolated, being decomposed when the salts are treated with a stronger acid. The chlorinated and brominated isatins yield corresponding compounds under the influence of alkalis and sulphurous acid.

Isatosulphite of Ammonium, $C^8H^6(NH^4)NO^3.2SO^2$, is obtained by boiling isatin with acid sulphite of ammonium, and concentrating the liquid by evaporation. It then separates in small rhomboïdal tables of a pale yellow colour, sparingly soluble in cold, but very soluble in boiling water.

Isatosulphite of Potassium, $C^8H^6KNO^3.2SO^2$, is produced by passing sulphurous anhydride to saturation into a solution of isatin in potash, or into a solution of isatate of potassium, or by boiling powdered isatin with acid sulphite of potassium, till it is completely dissolved.

The salt is neutral, has a faint yellow colour, is moderately soluble in water, and crystallises therefrom in elongated laminæ possessing considerable lustre. It is moderately soluble in boiling alcohol, very little in cold alcohol. Its solutions are yellow. When heated it aquires an orange-red colour, swells up and gives off water, and at a higher temperature blackens, and gives off a red thick matter, which solidifies without crystallising.—Iodine decomposes it at the boiling heat, isatin being precipitated and sulphuric acid remaining in the liquid. Chlorine also forms sulphuric acid, but at the same time throws down chlorisatin or dichlorisatin, according to the duration of the action. Hydrochloric acid poured into a boiling solution of the salt eliminates sulphurous anhydride, with effervescence, and precipitates isatin.

The solution of the potassium-salt does not form any precipitate with chloride of barium, strontium, or calcium, or with acetate of copper; but with nitrate of silver and acetate of lead, it forms precipitates consisting of a metallic sulphite, together with isatin.

Dibromisatosulphite of Potassium, $C^8H^4Br^2KNO^3.2SO^2$, is a yellow precipitate, sparingly soluble in water.

Chlorisatosulphite of Potassium, $C^8H^5ClKNO^3.2SO^2$, is obtained by passing sulphurous anhydride into a solution of chlorisatate of potassium. The liquid yields by evaporation a straw-yellow, fibro-lamellar salt, sparingly soluble in cold water. Acids decompose it, with precipitation of chlorisatin and evolution of sulphurous anhydride.

Dichlorisatosulphite of Potassium, $C^8H^4Cl^2KNO^3.2SO^2$. Yellow needles obtained by boiling dichlorisatin with acid sulphite of potassium.

ISATYDE. $C^{16}H^{12}N^2O^4 = (C^8H^5NO^2)^2.H^2$. (Laurent, Ann. Ch. Phys. [3] iii. 32.—Gm. xiii. 98.—Gerh. iii. 551.)—A substance produced by the action of reducing gents, such as nascent hydrogen, sulphydric acid, sulphide of ammonium, &c. on atin; *e.g.*:

$$\underset{\text{Isatin.}}{2C^8H^5NO^2} + H^2S = \underset{\text{Isatyde.}}{(C^8H^5NO^2)^2.H^2} + S.$$

bears to isatin the same relation that indigo-white bears to indigo-blue.

The best mode of preparing it is to mix powdered isatin in a flask with a large uantity of water and a little sulphuric acid, then add a piece of pure zinc-foil, and eat the liquid. As the isatin dissolves, it takes up the nascent hydrogen, and is con-rted into pulverulent isatyde, which may be washed with water, and then boiled with cohol to remove undecomposed isatin. Isatyde may likewise be obtained by dissolv-g isatin in hot alcohol, and adding a small quantity of sulphide of ammonium. The ixture left to itself for a week deposits laminated and prismatic crystals of isatyde, ixed with octahedral crystals of sulphur, which must be removed by digestion with sulphide of carbon.

Isatyde is white, with a slight greyish tint, tasteless, and inodorous, and appears to e insoluble in water. It dissolves in very small quantity, in alcohol and ether, at the oiling heat, and separates on cooling in microscopic scales, having the form of oblique isms with rectangular base.

Isatyde softens when heated, and then turns violet-brown (being perhaps converted to a mixture of indin and isatin); if the heat be increased till the body is half elted, it suffers further decomposition, yielding a substance which dissolves in alcohol d crystallises in brown-red needles by evaporation.

Boiling nitric acid decomposes isatyde, producing a violet powder which ultimately ssolves. Potash likewise decomposes it, forming isatate of potassium and indin-otassium, which ultimately changes to hydrindin-potassium and other products of nknown constitution (see p. 264).

Erdmann (J. pr. Chem. xxiv. 15) gives the name of *isatyde* to a substance which obtained by dissolving isatin in hot sulphide of ammonium. This substance gave analysis numbers agreeing approximately with the formula $C^{16}H^{12}N^2O^3$. It was hite, very slightly crystalline, scarcely soluble in water, but soluble in ammonia, with d colour gradually changing to yellow. Potash dissolved it with deep-red colour, dis-ppearing when the liquid was heated; the solution, on cooling, deposited a crystalline lt, and yielded yellow flocks with hydrochloric acid.

Chlorisatydes and **Bromisatydes.** (Erdmann, Ann. Ch. Pharm. xxxiii. 129. Laurent, Ann. Ch. Phys. [3] iii. 382.)—*Dichlorisatyde*, $C^{16}H^{10}Cl^2N^2O^4$, is pro-uced by the action of sulphide of ammonium on chlorisatin. It is white, crystallis-le, insoluble in cold water, sparingly soluble in hot water; moderately soluble in oiling alcohol, soluble also, apparently without alteration, in a hot solution of sulphide potassium. Heated to 180°, it is resolved into chlorisatin and chlorindin:

$$\underset{\text{Chlorisatyde.}}{2C^{16}H^{10}Cl^2N^2O^4} = \underset{\text{Chlorindin.}}{C^{16}H^8Cl^2N^2O^2} + \underset{\text{Chlorisatin.}}{2C^8H^4ClNO^2} + 2H^2O$$

Chlorisatyde is coloured red by *ammonia*, and partially dissolved. It dissolves in oiling aqueous *potash*, being converted into chlorisatate of potassium, which ystallises on cooling. The mother-liquor, treated with *hydrochloric acid*, yields a pious light-yellow precipitate, which is partially dissolved by boiling water, the inso-ble part consisting of chlorindin, and the dissolved portion of chlorisatydic acid, obably a product of the decomposition of chlorindin. This acid is deposited from e aqueous solution in the form of a lemon-yellow substance, which forms, with otash, a soluble salt having little tendency to crystallise. The solution gives, with lts of lead, copper and barium, yellow precipitates which redissolve in the liquid nen heated.

Tetrachlorisatyde, $C^{16}H^8Cl^4N^2O^2$.—Produced by the action of sulphide of mmonium on tetrachlorisatin. It resembles the preceding compound, and is decom-sed in like manner by heat into tetrachlorisatin and tetrachlorindin. It likewise haves in a similar manner when boiled with potash, yielding, among other products, obably by a secondary decomposition of dichlorindin, the potassium-salt of a peculiar id (*dichlorisatydic* acid) which, as the liquid cools, is deposited in yellow, shining minæ.

Tetrabromisatyde, $C^{16}H^8Br^4N^2O^2$, resembles tetrachlorisatyde, and is prepared a similar manner. It turns brown when heated, and is resolved into dibromisatin d dibromindin.

Sulphisatyde, $C^{16}H^{12}N^2O^2S$. *Sulphasathyde.* (Laurent, Ann. Ch. Phys. [3]

Digitized by Google

iii. 463).—Obtained by adding alcoholic potash drop by drop to an alcoholic sol of disulphisatyde:

$$\underset{\text{Disulphisatyde.}}{C^{16}H^{12}N^2O^2S^2} + KHO = \underset{\text{Sulphisatyde.}}{C^{16}H^{12}N^2O^2S} + KHS.$$

The liquid turns red, and after a few seconds deposits a white crystalline preci of sulphisatyde, which must be washed with boiling alcohol and dried. It gen has a faint rose tint, due to the presence of a small quantity of iodine.

Sulphisatyde when pure is a white, crystalline, inodorous, and tasteless powd crystallises from hot alcohol in microscopic rectangular scales. It is insoluble in Boiling *alcohol* dissolves only traces, which separate out on cooling in small cryst scales. It is not more soluble in *ether* than in alcohol.

Sulphisatyde, when *heated*, melts, turns red, swells up, and decomposes, while phuretted hydrogen is evolved, and a rose-coloured oil distils over, together wit vapour of a substance which crystallises in needles; finally, there remains a residue of charcoal. It is converted by *nitric acid* into a violet powder, in all probability, is nitrindin; the solution contains sulphuric acid. It is decom by cold *potash* with formation of various products, among which is indin; the so evolves sulphuretted hydrogen on the addition of hydrochloric acid, and gives cipitate consisting of sulphur and a little reddish matter. On treating sulphis with warm potash, hydrindin is formed.

Disulphisatyde. $C^{16}H^{12}N^2O^2S^2$. *Sulphésathyde.* (Erdmann, J. p. Chem. 16.—Laurent, Ann. Chim. Phys. [3] iii. 463.)—Produced by the action of sulph acid upon isatin.

The decomposition takes place in two stages, sulphur being first deposited isatyde produced, and this compound being afterwards converted into disulph with formation of water:

$$\underset{\text{Isatin.}}{2C^8H^5NO^2} + H^2S = \underset{\text{Isatyde.}}{C^{16}H^{12}N^2O^4} + S.$$

and

$$\underset{\text{Isatyde.}}{C^{16}H^{12}N^2O^4} + 2H^2S = \underset{\text{Disulphisatyde.}}{C^{16}H^{12}N^2O^2S^2} + 2H^2O.$$

Preparation.—When sulphydric acid gas is passed through a boiling concent alcoholic solution of isatin, the liquid becomes pale yellow, and forms a cryst deposit, which increases on cooling, and consists of microscopic sulphur-crystal scales (isatyde). The solution is left to itself for a week, that the greater part sulphur may crystallise out; it is then poured off and mixed with a little wate the resulting precipitate is removed, as it contains sulphur; it is then shaken up more water, which precipitates the disulphisatyde as a brownish grey resinou stance. (Laurent.)

Disulphisatyde, when dried, is a yellowish grey, inodorous, and tasteless po It does not crystallise from its alcoholic or ethereal solution, either on cooling spontaneous evaporation (Laurent). On drying at 110° it always becomes blu brick-red; if the solution is exposed to the air for some time before the additi water, the precipitate is brownish-red. (Erdmann.)

Disulphisatyde swells up strongly when heated in a glass tube, and melts, with tion of sulphydric acid; at the same time a brown oil and a needle-shaped subl are formed, and there remains a bulky residue of charcoal. When boiled with *nitric acid*, it puffs up, evolves pernitric oxide, and dissolves; water precipitates flakes from the solution. In boiling nitric acid diluted with its own bulk of wa puffs up and gives off nitrous fumes. If the reddish-brown swollen mass is t after a few minutes, with alcohol, the latter takes up a reddish substance, wh insoluble in water, but soluble in potash, from which it is precipitated by acids. portion insoluble in alcohol dissolves in potash, and on neutralising the solution an acid, a white precipitate, insoluble in water, is formed, consisting of micro needles. The liquid obtained by the action of nitric acid contains sulphuric aci no oxalic acid. *Bromine* acts violently upon disulphisatyde, with evolution of br of sulphur and hydrobromic acid, and forms a yellow mass containing bromind orange-yellow crystalline mass, and a little resin. Disulphisatyde dissolves in *sulphuric acid*, with the aid of a gentle heat; the red solution is not precipitat water; potash colours it green, but does not precipitate it. On treating disulphis with *potash*, sulphisatyde and various other products (amongst others, indin formed, which, however, cannot be produced at will. (According to Erdmann solution deposits a crystalline salt.) *Ammonia* behaves in a similar manner. *acid sulphite of ammonium*, at mean temperature, disulphisatyde produces v compounds, among which is found the ammoninm-salt of a peculiar acid, sulphisatanous acid. This salt is crystallisable, soluble in water and alcoho

dichloride of platinum, a yellow precipitate, which, acid, yields the free acid.

phisatyde is treated with acid sulphite of ammonium rally deposited a mixture of indin with a white sul- ned; sometimes, however, a different reaction takes of *isatan* (p. 404).

See TITANATES.

$^2SO^4 = C^2H^4.SO^4H^2$. (Gm. viii. 428.—Gerh. ii. 234.)
h ethyl-sulphuric (sulphovinic) acid, and may be re-
d, $\left.\begin{matrix}(C^2H^4)''\\(SO)''\\H^2\end{matrix}\right\}O^2$, was discovered by Magnus in 1833
as been further examined by Liebig, Regnault, olbe (Ann. Ch. Pharm. cxii. 241), and Carius (*ibid.*
By the ebullition of ethionic acid (ii. 523).—2. By lphuric acid, or of sulphuric anhydride, on alcohol or idues of the preparation of ether.—3. By the action H^7NSO^3, which may be regarded as the amic acid of rine in dilute nitric acid, treated with nitrite of potas- e of potassium. (W. Gibbs, Sill. Am. J. [2] xxv. 30.)
ulphuric anhydride is passed into absolute alcohol alt; and the resulting yellowish oily liquid is mixed and then saturated with carbonate of barium. The te of barium; if the water were added gradually, and te of barium would be produced, but no isethionate.— is passed for some time into anhydrous ether; water e excess of ether containing heavy oil of wine; and ion; it then gives off, first ether, then alcohol, and ulphuric and isethionic acids, which may be separated barium.

barium-salt is cautiously decomposed with the exact ired, and the filtrate is evaporated, first by gentle l of vitriol.

ly acid liquid, which decomposes acetates and common tion a heat of 150°, but blackens at higher tempera-

O^4, are obtained by decomposing the barium-salt with phates. They are soluble and crystallisable, and are phates, with which they are isomeric, by their much ustaining, without alteration, a temperature of 200°. with caustic potash, hydrogen is evolved, and there xalate, sulphate, and sulphite, the proportion of these of heat which has been applied. Isethionate of potas-

e of phosphorus, yields $C^2H^4SO^2Cl^2$, or $\left.\begin{matrix}(C^2H^4)''\\(SO)''\end{matrix}\right\}O\ Cl^2$,
es with ammonia, yields taurine (Kolbe):

$H^3 + H^2O = C^2H^7NSO^3 + 2HCl$.

$H^3(NH^4)SO^4$, forms well-defined octahedrons, which vacuum, and do not lose weight at 120°.

, crystallises in transparent six-sided plates, which oss of weight. They melt at 320°, and decompose at ng, swelling up to more than 100 times its original f very pungent odour.

$2H^2O$, forms pale-green right prisms with rhombic es resting upon the acute edges. At 140° it turns water of crystallisation.

, forms rhomboidal prisms which are unalterable in position a heat of 300°. It melts between 300° and n cooling, solidifies into a fibrous mass having the diminished in weight. The salt crystallises readily

A compound isomeric with biuret (i. 600), produced rom-acetyl-carbamide:

$+ NH^3 = \underset{\text{Isobiuret.}}{C^2H^5N^3O^2} + \underset{\text{Bromo-form.}}{CHBr^3}$

It dissolves sparingly in cold, easily in hot water, and crystallises from the solution in long needles containing $C^2H^5N^3O^2.2H^2O$, and melting at 185°, whereas biuret forms indistinct crystalline aggregations, and melts at 177°. In all other respects, the two substances resemble each other exactly. (A. Baeyer, Ann. Ch. Pharm. cxxx. 154.)

ISOBROMOMALEIC ACID. See MALEIC ACID.

ISOCAJPUTENE. See CAJPUTENE (i. 311).

ISOCETAMIDE. See the next article.

ISOCETIC ACID. $C^{15}H^{30}O^2$.—An acid discovered in 1854 by Bouis (Compt. rend. xxxix. 923). It is produced by saponifying the oil of *Jatropha Curcas* (huile de médicinier), the quantity obtained being 18 or 20 per cent. of the weight of the oil. After separation by pressure from oleic acid, and crystallisation from alcohol, it forms shining scales which melt at 55°, and solidify again at 53·5°. Its *silver-salt* is soluble in water, very soluble in alcohol, melts when heated, and burns easily without odour, leaving a residue of metallic silver.

Isocetate of Ethyl, $C^{15}H^{29}(C^2H^5)O^2$, prepared by the usual methods, is odourless, melts at the heat of the hand, and solidifies at 21°, remaining perfectly transparent, and assuming a crystalline structure.

Isocetamide, $C^{15}H^{31}NO$, is obtained by heating the oil above mentioned with ammonia in a sealed tube. It is white, nacreous, melts at 67°, and is not attacked by strong potash.

ISOCYANURIC ACID. Syn. with FULMINURIC ACID.

ISODIBROMOSUCCINIC ACID. See SUCCINIC ACID.

ISODIGLYCOL-ETHYLENIC ACID. $C^6H^{10}O^6$. (Barth and Hlasiwetz, Ann. Ch. Pharm. cxxii. 96).—An acid isomeric with diglycol-ethylenic acid (ii. 914), produced by treating milk-sugar with bromine and the product with oxide of silver. A bromine-compound of milk-sugar, $C^6H^{10}O^5Br^2$, (not isolated) appears to be first formed; and this when treated with moist oxide of silver yields bromide of silver, and the acid, $C^6H^{10}O^6$.

The acid is prepared by heating 30 grms. milk-sugar (1 at. = $C^6H^{10}O^5$) with 60 grms. bromine and half a litre of water, to 100° in strong well-closed bottles. The somewhat dilute yellowish solution is neutralised with moist oxide of silver (or oxide of lead); and the filtered solution is decomposed by sulphydric acid, evaporated at a gentle heat, mixed with alcohol to remove a little lime, freed from alcohol by distillation, and saturated, while still hot, with carbonate of cadmium. The slightly acid solution, decolorised with animal charcoal, yields the cadmium-salt in groups of granular crystals. To obtain the free acid, the cadmium-salt is rubbed up to a thin paste with water, and decomposed while hot by sulphydric acid, and the filtrate is evaporated to a syrup, which gradually dries up to a soft, hygroscopic, crystalline mass.—This acid may also be obtained, without the formation of the intermediate bromine-compound, by treating milk-sugar with half the preceding quantity of bromine, neutralising the solution with carbonate of sodium, and boiling.

An acid, agreeing with the preceding in every respect excepting the amount of its rotatory power, is obtained in like manner from gum-arabic. With starch only, a small quantity of an uncrystallisable acid mass is obtained. Mannite, cane-sugar and glucose, treated with bromine and water, form hydrobromic acid, which then gives rise to the formation of humus-like products.

Isodiglycol-ethylenic acid dried over oil of vitriol contains 13·9 per cent. water, agreeing nearly with the formula, $2C^6H^{10}O^6.3H^2O$. It has a strong acid reaction, melts below 100°, and burns on platinum-foil, giving off the odour of burnt sugar. It dissolves in alcohol and is precipitated from the solution in flocks by ether. The aqueous solution is not precipitated by neutral or basic acetate of lead, mercuric nitrate, caustic baryta, or lime-water, but forms a white precipitate with ammoniacal sugar of lead. The ammonium-salt reduces an alkaline cupric solution, and forms a speculum when heated with nitrate of silver. The acid possesses optical rotatory power.

Isodiglycol-ethylenate of ammonium, $C^6H^9(NH^4)O^6.H^2O$, crystallises in large, transparent, glassy crystals of the monoclinic system. It dissolves in water, is nearly insoluble in alcohol, and gives off all its water at 120°.

The *cadmium-salt* crystallises from a hot-saturated solution in granular aggregates of monoclinic needles containing $C^{12}H^{18}Cd''O^{12}.3H^2O$; from dilute solutions, or from the mother-liquor by slow evaporation, in well-developed monoclinic crystals, mostly united in tufts. Both these hydrates, especially the former, are sparingly soluble in water, and both retain all their water of crystallisation till heated to 150°.

The *calcium-salt*, $C^{12}H^{18}Ca''O^{12}.7H^2O$, crystallises in crusts, or from more dilute solutions in large shining plates; it gives off 4 at. water at 100°, and the rest at 140°. There is also a calcium-salt containing only half as much water as the preceding.

The *barium-* and *strontium-salts* are gummy.

Digitized by Google

The *copper-salt* is soluble and amorphous.

A *lead-salt* having approximately the composition, $C^{12}H^{16}Pb''O^{12}.4Pb''O.H^2O$, is obtained as a white precipitate on treating the solution of the acid with neutral acetate of lead and ammonia.

The *potassium-salt* forms a viscid uncrystallisable mass, easily soluble in water, and precipitated by alcohol.

The *silver-salt* is a gelatinous, easily decomposible precipitate, formed only in concentrated solutions.

The *sodium-salt* forms tufts of prisms, which in the air-dried state contain $C^6H^7NaO^6.2H^2O$, and give off half their water at 100°.

ISOMERISM. This term is derived from *ἴσος* equal, and *μέρος* part, and its employment by chemists is an expression of the fact that very different chemical compounds have sometimes identically the same ultimate composition.

Two or more different bodies which are composed of the same elements, and of the same proportions of those elements (*i.e.* which have the same percentage composition) are said to be isomeric.

Isomerism is sometimes used in a narrower sense, being made to signify equality of molecular weight, as well as identity in percentage composition. When the compounds have the same percentage composition but different molecular weights, the term polymeric is employed. Thus there are the terms *Isomeric* (in its wide sense), signifying that the different bodies have the same percentage composition; *Polymeric*, signifying that these different bodies have the same percentage composition, but different molecular weights; *Isomeric* (in its restricted sense), sometimes called *Metameric*, that the bodies have the same percentage composition and likewise the same molecular weight.

As might naturally be expected, cases of isomerism abound in organic chemistry, where an enormous number of compounds result from the combination of very few elements. The following organic substances may be cited by way of illustrating the employment of the term isomeric and its congeners.

Butyric acid	$\left.\begin{matrix}C^4H^7O\\H\end{matrix}\right\}O = C^4H^8O^2$
Acetic ether	$\left.\begin{matrix}C^2H^3O\\C^2H^5\end{matrix}\right\}O = C^4H^8O^2$
Aldehyde	$\left.\begin{matrix}C^2H^3\\H\end{matrix}\right\}O = C^2H^4O$
Oxide of ethylene	$(C^2H^4)''O = C^2H^4O$

These four bodies are quite different, and have the same percentage composition, viz.:

Carbon	54·55
Hydrogen	9·09
Oxygen	36·36
	100·00

They are *Isomeric*, or *Isomers*, using the term in its widest sense.

Again, butyric acid and aldehyde have different molecular weights:—

Butyric acid	$C^4H^8O^2 = 88$
Aldehyde	$C^2H^4O = 44$

Butyric acid and aldehyde are therefore *Polymeric*.

Similarly acetic ether and aldehyde are *Polymeric*, or acetic ether and oxide of ethylene are *Polymeric*, or butyric acid and oxide of ethylene are *Polymeric*.

Again, butyric acid and acetic ether have the same molecular weights, viz.:

Butyric acid	$C^4H^8O^2 = 88$
Acetic ether	$C^4H^8O^2 = 88$

They are therefore *Isomeric* (in the restricted sense) or *Metameric*. Aldehyde and oxide of ethylene are also metameric bodies.

Closely related to the term isomerism is the term allotropy. Both of them have reference to the same substantial fact, viz. that different substances have sometimes the same ultimate composition; but they differ in their manner of stating it. Isomeric and allotropic are in fact complementary terms, "isomeric" being employed to predicate identity of composition between different bodies, whilst "allotropic" expresses difference between bodies of identical composition.

Such being the force of these words, there is a certain propriety in their usage; thus whilst it is correct to say, "Butyric acid and acetic ether are *isomeric*," it should be "There are *allotropic* bodies of the formula, C^6H^7N." The same reason which enjoins the use of "allotropic" in this case, prescribes it in the instance of single elements; thus, for example, we read of "allotropic kinds of sulphur," but never of isomeric kinds.

It is worthy of remark that cases of isomerism occurring in inorganic chemistry, are

Digitized by Google

usually described by employing the word allotropy or allotropic, whilst obtains in organic chemistry. This may be partly ascribed to there bei very wide difference—or else no difference at all—in the composition of inorganic substances; and hence the fact of identity or non-identity of being so easily ascertainable, it is implied in the form of expression, whils difference of properties alone needs to be made the subject of formal Among organic bodies, on the other hand, it continually happens that th of composition are quite decided, and yet so very minute as to tax the ut of chemical analysis for their recognition; and hence the superior dignit mere affirmation of identity of ultimate composition acquires in the org ment of the science.

The principal examples of allotropy or isomerism, *i.e.* of the coexistence ultimate composition with difference of properties, will now be considered.

Hydrocarbons.—1. The **olefines**, a numerous class having the gene C^nH^{2n}, form a very remarkable case of polymerism. Methylene, the lowest $n=1$, is wanting, and appears to be an impossible body; for many reactio it should be produced yield the higher terms instead. The olefines at pre are:

		Vapour-density.	B
Ethylene	C^2H^4	0·97	
Propylene	C^3H^6	1·45	
Butylene	C^4H^8	1·94	
Amylene	C^5H^{10}	2·42	
Hexylene	C^6H^{12}	2·91	
Heptylene	C^7H^{14}	3·39	
Octylene	C^8H^{16}	3·87	
Decatylene (paramylene)	$C^{10}H^{20}$	4·84	
Cetylene	$C^{16}H^{32}$	7·75	

By the destructive distillation of wax, Brodie obtained cerotene, for which $C^{27}H^{54}$ has been given; but there is in reality no reason whatever why C than any other out of a considerable number of formulæ, should be assigne

The percentage composition of the olefines is

Carbon	= 85·72
Hydrogen	= 14·28
	100·00

They present a certain general chemical character. All of them combin rine and bromine with great readiness. They differ in vapour-density, th beginning of the list increasing regularly in vapour-density by 0·4844. The gaseous at ordinary temperature and pressure; the third is a very volatile li at about 0° C.; the others on the list are liquids of which the boiling-point formula increases; and the very complex olefines which, being uncertain, ar list are usually believed to be solids. It will be observed that the increme point for the addition of CH^2 to the formula is large; between amylene an for instance, it is 34°. As the series is ascended, the increment become successively smaller and smaller.

The specific gravity of the different olefines in the liquid state seems to the formula increases.

There are certain well ascertained chemical differences between the olef the amount of olefine which will saturate a given quantity of chlorine, or differs according to the olefine taken, being proportional to the vapour-de molecular weights of the different olefines express their saturating capaci the vapour-densities are proportional to the molecular weights.

Each olefine may be prepared from a peculiar alcohol, and in general m to yield that peculiar alcohol by certain simple processes, *e. g.*:

Ethylic alcohol.				Ethylene.
C^2H^6O	–	H^2O	=	C^2H^4
Amylic alcohol.				**Amylene.**
$C^5H^{12}O$	–	H^2O	=	C^5H^{10}

and again:

Ethylene.				Ethylic alcohol.
C^2H^4	+	H^2O	=	C^2H^6O
Amylene.				**Amylic alcohol.**
C^5H^{10}	+	H^2O	=	$C^5H^{12}O$.

If the alcohol and the olefine standing in these relations to it be comp be seen that they resemble one another in the number of carbon-atoms conta molecules.

but much remains to be done before any very positive opinion can be formed of nature of the metamerism subsisting between this mannite-hydride and the commo hexyl-hydride.

3. Two compounds with the empirical formula CH, viz. benzene and acetylene, p sent a curious case of polymerism.

These compounds have a certain likeness, both being products of the action very elevated temperature, but in other respects they are very unlike.

Benzene, C^6H^6, is a liquid, and is related to benzoic acid and phenylamine. Acetyle C^2H^2, is a gas possessing the peculiar property of attacking certain metallic solutio such as ammoniacal solution of cuprous chloride, and is related to common alcohol.

4. A large number of volatile oils differing much in smell, taste, boiling-po action with reagents, and in other important particulars, have had the formula C^{10} assigned to them. To this class belong the different kinds of oil of turpentine, oil lemons, neutral oil of cloves, oil of elemi-resin, carvene, and some others. Respect these bodies, the remark may be made that we are, for the most part, quite ig rant of their true formula: for, in the almost entire absence of derivatives, the m analysis of such hydrocarbons by our present methods is totally inadequate to dist guish between a variety of non-isomeric formulæ, all equally probable.

Isomers containing Carbon, Hydrogen, and Oxygen.

Both metamerism and polymerism occur very abundantly among these compoun

(1.) The ethers of the organic acids afford room for endless metamerism, as will apparent on a little consideration.

Acetate of methyl, $\left.\begin{matrix}C^2H^3O\\CH^3\end{matrix}\right\}O$, is metameric with formate of ethyl, $\left.\begin{matrix}CHO\\C^2H^5\end{matrix}\right\}O$, and w propionic acid, $\left.\begin{matrix}C^3H^5O\\H\end{matrix}\right\}O$. It is obvious that if we subtract nCH² from the acid-for ing radicle and add nCH² to the alcohol-forming radicle, or *vice versâ*, we must ge metamer. Hence it follows that any ether of an organic acid must have many metame if its molecular weight be tolerably high. Here is an example:—

Valerate of amyl	$\left.\begin{matrix}C^5H^9O\\C^5H^{11}\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$
Butyrate of hexyl . . .	$\left.\begin{matrix}C^4H^7O\\C^6H^{13}\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$
Propionate of heptyl . . .	$\left.\begin{matrix}C^3H^5O\\C^7H^{15}\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$
Acetate of octyl	$\left.\begin{matrix}C^2H^3O\\C^8H^{17}\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$
Formate of nonyl . . .	$\left.\begin{matrix}CHO\\C^9H^{19}\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$
Caproate of tetryl . . .	$\left.\begin{matrix}C^6H^{11}O\\C^4H^9\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$
Œnanthate of trityl . . .	$\left.\begin{matrix}C^7H^{13}O\\C^3H^7\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$
Caprylate of ethyl . . .	$\left.\begin{matrix}C^8H^{15}O\\C^2H^5\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$
Pelargonate of methyl . .	$\left.\begin{matrix}C^9H^{17}O\\CH^3\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$
Rutic acid	$\left.\begin{matrix}C^{10}H^{19}O\\H\end{matrix}\right\}O$	= $C^{10}H^{20}O^2$

Thus there are no fewer than nine metamers of valerate of amyl. The differen between metamers of this kind is very neatly defined by reactions, saponificati with potash yielding a different alcohol and a potassium-salt of a different acid in ea case. For example, valerate of amyl gives amyl-alcohol and valerate of potassiu whilst butyrate of hexyl gives hexyl-alcohol and butyrate of potassium.

This kind of metamerism is of course, not confined to the fatty-acid series: whenev there are homologues of the acids—no matter what the series to which the acid belon —such metamerism is possible. And of course the same remark applies to the alcoh the aromatic and the allylic series admitting of just the same kind of metamerism the vinic series.

(2.) Every alcohol in a series, except the lowest one, is metameric with one or mo ethers, thus:—

Common alcohol	$\left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O$	= C^2H^6O

Digitized by Google

Methyl-ether . . . . . $\left.\begin{matrix}CH^3\\CH^3\end{matrix}\right\}O$ = C^2H^6O.

r up in the scale:—

Amyl-alcohol . . . . . $\left.\begin{matrix}C^5H^{11}\\H\end{matrix}\right\}O$ = $C^5H^{12}O$

Cetryl-methyl ether . . . . . $\left.\begin{matrix}C^{15}H^{31}\\CH^3\end{matrix}\right\}O$ = $C^{16}H^{34}O$

Trityl-ethyl ether . . . . . $\left.\begin{matrix}C^{19}H^{15}\\C^2H^5\end{matrix}\right\}O$ = $C^{21}H^{20}O$.

ction of iodide of phosphorus upon these different compounds enables us to dis- them immediately.

The aldehydes are metameric with ketones, with alcohols of the allylic series, ethers of the glycol series, thus:

Propylic aldehyde . . . . . $\left.\begin{matrix}C^3H^4O\\H\end{matrix}\right\}$ = C^4H^6O

Common acetone . . . . . $\left.\begin{matrix}C^3H^3O\\CH^3\end{matrix}\right\}$ = C^4H^6O

Allylic alcohol . . . . . $\left.\begin{matrix}C^3H^5\\H\end{matrix}\right\}O$ = C^3H^6O

Oxide of tritylene . . . . . $(C^3H^5)''O$ = $C^6H^{10}O$.

four compounds are very easily distinguished from one another: the first is idised to propionic acid; the second gives no propionic acid on oxidation, but ty acids instead; the third gives acrolein and acrylic acid; the fourth lactic

Ketones are metameric with other ketones and with aldehydes and compounds ic therewith.

metamerism with other ketones is very easy to understand. The rational formula tones consisting of an acid-forming radicle conjoined with an alcohol-forming t follows that transference of nCH^2, from one radicle to the other will yield bodies. Thus, for instance, we have isomers in

Ethyl-valeryl . . $\left.\begin{matrix}C^5H^9O\\CH^3\end{matrix}\right\}$ and Ethyl-butyryl . . $\left.\begin{matrix}C^4H^7O\\C^2H^5\end{matrix}\right\}$

nowledge of the ketones is very slight, but it is to be expected that these two ds would give different products on being oxidised.

meric Alcohols.—It has recently been discovered that there are at least two alcohols, the corresponding terms of which are metameric, well-marked differ- ving been recognised between compounds with the composition of hexylic and also between compounds with the composition of amylic alcohol. It is at ncertain what the nature of this metamerism is (see HEXYL-ALCOHOLS, p. 152), ems to affect the total constitution of the two sets of compounds.

e superficial kind of difference was noticed by Pasteur, some years ago, be- rieties of amylic alcohol. Ordinary fusel-oil was found by Pasteur to be made o liquids having the composition of amylic alcohol, but slightly different in es, the one being without action on polarised light, whilst the other turned the a polarised ray to the left. The derivatives of each of these varieties of lcohol possess the same action on polarised light as the alcohols themselves, sent some differences in solubility, &c., but on the whole they are marvellously Chemists are not agreed how these varieties are to be regarded, it being still n whether a mere difference in action upon polarised light points to any but the htest difference in constitution.

meric Acids.—There is some reason for believing that the fatty acids, when in the liquid state, have twice the molecular weight which their vapours have ated up to 300° and higher. Their great tendency to form double salts, and hat their vapours at low temperature—whether under great or small pressure— ouble density, point to this conclusion.

ting the double formula for the fatty acids, some very interesting cases of ism arise. Thus, propionic acid is metameric with butyr-acetic acid:—

Propionic acid . . . $\left.\begin{matrix}C^3H^5O\\C^3H^5O\\H^2\end{matrix}\right\}O^2$ = $C^6H^{12}O^4$,

Butyr-acetic acid . . . $\left.\begin{matrix}C^4H^7O\\C^2H^3O\\H^2\end{matrix}\right\}O^2$ = $C^6H^{12}O^4$,

Digitized by Google

and, in like manner, each term of the series, except the end ones, is metameric with compound acid formed of the next below united with the next above. It is worth of remark, as a fact in the history of organic chemistry, that butyr-acetic acid wa mistaken for, and described as, propionic acid.

The anhydrides of the aromatic and fatty acids offer a systematic metamerism, *e.g.*

Aceto-valeryl anhydride . . $\left.\begin{matrix}C^2H^3O\\C^5H^9O\end{matrix}\right\}O = C^7H^{12}O^3$,

and

Propio-butyryl anhydride . $\left.\begin{matrix}C^3H^5O\\C^4H^7O\end{matrix}\right\}O = C^7H^{12}O^3$,

are metameric. In fact there is, among these anhydrides, just a repetition of the cas of the ethereal-salts of the organic acids; by making nCH^2 move from the one radicl to the other, endless metamerism arises.

No case of metamerism between two single fatty acids has yet been made out; bu in the aromatic series, there are such cases: thus there are two benzoic acids.

A very remarkable example of metamerism is afforded by the different varieties c tartaric acid and racemic acid. There is a tartaric acid which polarises to the righ (the commonest), another which polarises to the left; racemic acid, from which bot varieties of tartaric acid may be obtained; and, finally, a tartaric acid without an action upon polarised light. All these substances are metameric, having the formul

$$C^4H^6O^6.$$

Polyatomic Alcohols.—Mannite and melampyrin are metameric, both of them havin the formula

$$C^6H^{14}O^6.$$

The most striking difference between these bodies is to be found in their degrees c solubility in water—mannite being comparatively soluble, melampyrin comparativel insoluble. In reactions they are, so far as is known, very similar.

There seem to be many metamers both of grape-sugar and of cane-sugar, but littl is known with certainty respecting them.

Examples of polymerism are not by any means so numerous among the compound of carbon, hydrogen, and oxygen, as we have found the examples of metamerism to be There can be no polymers either of the vinic alcohols or vinic ethers.

The fatty acids, and the ethers of the fatty acids, are polymeric with more comple acids, or with compounds of the sugar-class; but even among them, there is nothin approaching to the endless metamerism which has been referred to.

Acetic acid offers one of the best examples of a fatty acid polymeric with severa substances:

$2(CH^2O) = C^2H^4O^2$, acetic acid,
$3(CH^2O) = C^3H^6O^3$, lactic acid,
$6(CH^2O) = C^6H^{12}O^6$, grape-sugar.

By doubling the formula of any aldehyde, we get the formula of a fatty acid, thus:

C^2H^4O, common aldehyde,
$C^4H^8O^2$, butyric acid.

By tripling the formula of an aldehyde, we get the formula of an acid of the lacti series, *e.g.*:

C^2H^4O, common aldehyde,
$C^6H^{12}O^3$, leucic acid.

Grape-sugar is polymeric with ethyl-carbonic acid: Grape-sugar = $C^6H^{12}O^6$; 2 mole cules of ethyl-carbonic acid = $2.\left.\begin{matrix}CO\\C^2H^5\\H\end{matrix}\right\}O^2 = 2C^3H^6O^3 = C^6H^{12}O^6$.

Isomers containing Carbon, Hydrogen, and Nitrogen.

(1.) *Metamerism among the compound ammonias.*

The following compound ammonias have the formula $C^6H^{15}N$:—

Hexylamine . . . . $\left.\begin{matrix}C^6H^{13}\\H\\H\end{matrix}\right\}N = C^6H^{15}N$

Amyl-methylamine . $\left.\begin{matrix}C^5H^{11}\\CH^3\\H\end{matrix}\right\}N = C^6H^{15}N$

Tetryl-ethylamine . . . $\left.\begin{matrix}C^4H^9\\C^2H^5\\H\end{matrix}\right\}N = C^6H^{15}N$

Digitized by Google

mine . . $\left.\begin{matrix}C^6H^9\\CH^3\\CH^3\end{matrix}\right\}N = C^8H^{15}N$

. . . $\left.\begin{matrix}C^5H^7\\C^3H^7\\H\end{matrix}\right\}N = C^8H^{15}N$

ylamine . $\left.\begin{matrix}C^3H^7\\C^2H^5\\CH^3\end{matrix}\right\}N = C^8H^{15}N$

. . . $\left.\begin{matrix}C^2H^5\\C^2H^5\\C^2H^5\end{matrix}\right\}N = C^8H^{15}N.$

uishes the different compound ammonias from one h nitrous acid, they give up their different alcohol- For example, the first base on our list, hexylamine, exyl-alcohol; the second, amyl-alcohol and methyl- and ethyl-alcohol, &c.

iethylamine has six distinct metamers: but if, as is e of the three atoms of hydrogen in ammonia has a tamers of triethylamine will become very numerous

her we go—the higher the molecular weight of a base

ossible metamers. Thus tricetylamine, $\left.\begin{matrix}C^{16}H^{33}\\C^{16}H^{33}\\C^{16}H^{33}\end{matrix}\right\}N$, has

of which should give a different result with nitrous

netamerism, due to the presence of different alcohol- other kinds of metamerism among the compound

ll-known case of the bases parallel with phenylamine,

= C^8H^7N = Picoline
= C^7H^9N = Lutidine.
&c. &c.

metamerism in this case is that phenylamine is a deri- picoline is derived from a hydrocarbon C^6H^{10}.

amine = $(C^6H^5)'NH^2$
= $(C^6H^7)'''N$.

e of the difference in constitution between these two s is very striking:

61;
e, &c. on
oxidising

Picoline boils at 135°:
most pungent and bad smell:
very soluble in water:

d much further.

meric with the foregoing has been discovered. The ies is β-lutidine, which is obtained by the destructive s less soluble in water than common lutidine, boils ell, &c.

f nitrogen to coalesce and form a group requiring either atives for its saturation. Three or even four atoms of the bases so resulting there must be almost infinite

ompounds of Carbon, Hydrogen, and Nitrogen.

ne are polymeric, the formula of the latter being three

N = Cyanide of ethyl.
$^5N^3$ = Cyanethine.

Digitized by Google

The former is a liquid, the latter a solid possessing the properties of a weak base. It is probable that the rational formula of the latter is:

$$N^3\begin{cases}C^3H^{5'''}\\C^3H^{5'''}\\C^3H^{5'''}\end{cases}$$

It will be obvious that the existence of compound ammonias containing more than one atom of nitrogen in the molecule opens the door for much polymerism.

Isomers containing Carbon, Hydrogen, Nitrogen, and Oxygen.

The metamerism between cyanate of ammonium and urea, is one of the oldest known.

Cyanate of ammonium . . . . . $\begin{matrix}CN\\NH^4\end{matrix}\Big\}O = CH^4N^2O$

Urea . . . . . $\begin{matrix}CO''\\H^4\end{matrix}\Big\}N^2 = CH^4N^2O.$

Although cyanate of ammonium is transformed spontaneously into urea, yet there is a very great difference between the characters of the two compounds. One striking difference between a solution of a cyanate and a solution of urea is the comparative stability of the latter.

Glycocine and nitrite of ethyl are metameric:

Glycocine . . . . . $\begin{matrix}C^2H^2NH^2O\\H\end{matrix}\Big\}O = C^2H^5NO^2,$

Nitrite of Ethyl . . . . . $\begin{matrix}NO^2\\C^2H^5\end{matrix}\Big\} = C^2H^5NO^2,$

but are utterly different in properties. Glycocine (sugar of gelatin) is a crystalline solid. Nitrite of ethyl is a liquid.

Anthranilic acid	$C^7H^7NO^2$
Benzamic acid	$C^7H^5NH^2O^2$
Salicylamide	$C^7H^5NH^2OO$
Nitrotoluene	$C^7H^7NO^2$

are metameric.

Besides these, there are many more examples of metamerism among compounds of carbon, hydrogen, nitrogen, and oxygen, but we need not particularise them.

Polymerism also occurs in abundance. A very frequently cited example of this is afforded by

Cyanic acid	CHNO
Cyanuric acid	$C^3H^3N^3O^3$

Fulminic acid, $C^2H^2N^2O^2$, is also polymeric with the above, but it is only known in the form of its salts—not in the free state.

Organic Isomers containing various elements in addition to the so-called Organic Elements.

They are very abundant. A good example of metamerism between chlorinated compounds is afforded by dichloride of ethylene and chloride of monochlorethyl:

Dichloride of ethylene, $(C^2H^4)''Cl^2$,
boils at 85°;
specific gravity at 18° = 1·247;
with alcoholic solution of potash, gives $C^2H^3Cl + HCl$;
with sodium in presence of ether gives $C^2H^4 + 2NaCl$;

Chloride of monochlorethyl, C^2H^4ClCl;
boils at 64°;
specific gravity at 17° = 1·174;
with alcoholic solution of potash, hardly any reaction;
with potassium gives no reaction.

A very interesting case, from the extreme simplicity of the compounds, is to be found between the chlorine-derivative obtained by direct action of chlorine on marsh gas, and common chloride of methyl. Both of these compounds have the empirical molecular formula, CH^3Cl, and both are gaseous at ordinary temperatures and pressures, but they possess some unmistakable differences in properties.

There are corresponding brominated compounds—Bunsen obtained a gas from bromhydrate of cacodylic acid. The composition of the gas is the same as that of bromide of methyl, viz., CH^3Br; but whilst bromide of methyl is a liquid boiling at 13°, Bunsen's brominated gas does not liquefy below −17° C.

Many more cases of isomerism among these semi-organic and semi-inorganic compounds might be cited.

Digitized by Google

Isomers among Inorganic Substances.

s before remarked, the instances of inorganic isomerism are usually called instances llotropy—isomeric substances and allotropic substances being nearly equivalent ex- sions.

he elementary substances themselves offer many examples of isomerism. Thus gen appears to be capable of existing in two allotropic states; in one condition it is wn as ordinary oxygen, in the other as ozone. Ozone and oxygen are isomeric ies. Formula for oxygen = O^2; formula for ozone = O^4(?) Experiment has wn that the molecular formula for ozone is higher than that for oxygen; but how h higher remains an open question.

ulphur, phosphorus, carbon, and many other elements present *somewhat* similar mples of allotropy or isomerism.

norganic compounds, such as the various forms of silicic acid, of sesquioxide of iron, esquioxide of chromium, of alumina, must be classed among substances affording mples of isomerism.

here seem to be two allotropic states of peroxide of nitrogen. The compound NO^2 deeply-coloured gas at 100°. The compound N^2O^4 is a liquid boiling a little w 30°. Its vapour-density is double that of the former body. Altogether, in- anic isomerism is a very wide, but as yet a very ill-explored field.

he explanation of the existence of isomerism will have become sufficiently clear n the course which has been followed in describing the different examples of it. is of consequence how the atoms of a compound are arranged as well as what kind atoms they are," and hence there may be very many totally different substances posed of the same ultimate atoms. This is in fact the whole philosophy of iso- ism.

J. A. W.

SOMORPHISM. (*Ἴσος*, equal, and *μορφή*, form.) Crystalline form affords, as is l known, one of the most valuable physical distinctions between different substances, much as each element, and each compound, crystallises for the most part in forms ch are reducible to one or two primary forms. Hauy, who first directed attention he importance of this character, laid it down as a general law, that every substance has a nary crystalline form peculiar to itself, and therefore that a difference in the primary ns of two crystals may always be taken as evidence of difference of composition. towards the end of the last, and the beginning of the present century, various ervations were made tending to disprove the generality of this law. The similarity orm between phosphate of calcium (apatite) and phosphate of lead (pyromorphite) s noticed by Werner. Leblanc in 1787, showed that a mixed solution of ferrous l cupric sulphates deposits crystals containing both copper and iron, always of the ne form, but with considerable variations in the proportions of the two metals; also t alum containing a considerable quantity of ferric oxide crystallises exactly in the ne form as pure alumino-potassic sulphate. Vauquelin, in 1797, showed that the ne form is exhibited by alum, when it contains a considerable quantity of ammonia place of potash. Berthier, in 1806, pointed out the great similarity in the form of c-spar, bitter spar, and spathic iron—a resemblance confirmed by the more exact asurements of Wollaston; and Gay-Lussac, in 1816, showed that a crystal of ash-alum immersed in a solution of ammonia-alum increases in bulk without eration of form. These and other isolated observations of similar import may be d to have prepared the way for the establishment, by Mitscherlich, of the general v of isomorphism, which affirms that *bodies having a similar chemical constitution ve also the same crystalline form, as determined by the measurement of their angles*, or, other words, that *analogous elements and groups of elements may replace one another composition without essential alteration of crystalline form.* Mitscherlich's first servations, presented to the Berlin Academy of Sciences in 1819, related to the iso- rphism of the phosphates and arsenates, and showed that the corresponding salts of osphoric and arsenic acids containing equal numbers of atoms of water, crystallise in same forms. Similar observations were subsequently made upon the sulphates, enates, manganates, and chromates; the protosalts of magnesium, zinc, cadmium, anganese, iron, nickel, cobalt, and copper, and the sesquisalts of iron, aluminium, romium, and manganese, the corresponding salts being supposed in all cases to contain ual numbers of atoms of water.

Bodies having apparently an exactly similar constitution are not necessarily iso- rphous, but are rather divisible into two or more groups, of which the respective embers are isomorphous; on the other hand, the possession of an equal number atoms is not essential to isomorphism, for two atoms of one element are not unfre- ently isomorphous with one atom of another element; and sometimes a molecular oup is isomorphous in its combinations with an elementary atom—NH^4 with K, for

Digitized by Google

example. There are also numerous examples of bodies crystallising in the same forms, but without exhibiting any similarity of chemical constitution.

The corresponding angles of isomorphous bodies are not always precisely equal, but may differ from each other by one or two degrees. This discrepancy, however, is rendered unimportant by the circumstance, that the angles of different crystals of one and the same substance can present similar variations, under the influence of certain modifying causes.

It will of course be understood that the similarity of form in isomorphous bodies relates to the primary forms to which they are reducible; two crystals may be really isomorphous, and yet very different in external form, in consequence of being differently modified; thus calc-spar, bitter spar, and spathic iron have the same primary form; but each exhibits numerous modifications, some of which prevail chiefly in one, some in another, of these compounds.

The following table exhibits the most important and best established examples of isomorphism, arranged according to the crystallographic systems. Bodies crystallising in the same forms (*i. e.* reducible to the same primary form) are arranged in groups, numbered consecutively, without regard to the system to which the several forms belong; the subdivisions *a*, *b*, *c*, &c., include those also which correspond in atomic constitution.

odies occurring more than once in this table are dimorphous or trimorphous.
o each group of isomorphous bodies in the dimetric, trimetric, monoclinic, and inic systems, there corresponds a particular pyramid with its prisms and domes, to each group in the hexagonal system, a particular rhombohedron.
perfectly exact accordance of the crystalline forms of two chemically different es, occurs perhaps only in the monometric system. Bodies of the same group ch crystallise in other systems generally exhibit small differences in the correspond- angles. Thus, the angles of the terminal edges of the rhombohedrons of calcspar, logite, and the other isomorphous carbonates of group 11, exhibit the following rences:—

		R : R in terminal edges
Calcspar	$CaCO^3$	105° 5′
Dolomite	$\left\{\begin{matrix}Ca\\Mg\end{matrix}\right\}CO^3$	106° 15
Diallogite	$MnCO^3$	106° 51′
Spathic iron	$FeCO^3$	107° 0′
Magnesite	$MgCO^3$	107° 25′
Calamine	$ZnCO^3$	107° 40′.

n arragonite and the carbonates isomorphous therewith (group 17, *a*), the angles : ∞P in the macrodiagonal principal section, and P∞ : P∞ in the basal principal ion, have the following values:

		∞P : ∞P	P∞ : P∞
Arragonite	$CaCO^3$	63° 44′	71° 33′
Witherite	$BaCO^3$	61° 30′	73° 6′
Strontianite	$SrCO^3$	62° 44′	71° 48′
Cerusite	$PbCO^3$	62° 46′	71° 47′.

erfect equality in the corresponding angles of crystals is not always found, even in monometric system. The simpler forms of that system, namely, the cube, octa- ron, and rhombic dodecahedron, do not, of course, admit of any variation in the les; but the remaining forms, which are expressed by formulæ containing finite erical coefficients, viz. mOm, mO, $mO\infty$, and mOn, have different angles, according he numerical values of those coefficients; and, consequently, crystals of two dif- nt substances crystallising in one of these forms may exhibit slight differences in r angles, as well as isomorphous crystals belonging to other systems. With regard he three simpler forms of the monometric system, it may be observed that all bodies ch crystallise in them may be regarded as isomorphous in a certain sense, inasmuch all these forms are derivable one from the other; nevertheless, some bodies are e disposed to crystallise in one form than in the other, and a further distinction is rded by the cleavage; thus, zinc-blende, ZnS, cleaves parallel to the faces of a nbic dodecahedron; galena, PbS, parallel to the faces of a cube. Such bodies, in e of their similarity of form and atomic constitution, cannot be regarded as strictly norphous, at least in the same degree as NaCl and KCl, which agree in the direc- of their cleavage as well as in their form.
rom the similarity of form of two compounds, the isomorphism of certain of their stituents may often be inferred. If a compound, $a + b + c$, is isomorphous with ther, consisting of $a + b + d$, it may be concluded that c is isomorphous with d. example, the isomorphism of K^2PtCl^6 and K^2IrCl^6 leads to the conclusion that inum and iridium are isomorphous. In this manner, the isomorphism of the fol- ing groups of elements may be inferred:

. *Monometric Metals and Metalloids.* Carbon (diamond), phosphorus, potassium, um, titanium, cadmium, lead, iron, copper, silver, gold, platinum, palladium, iridium, zinc (Table I, group 1, *a*),—manganese, calcium, lithium, ammonium, nickel, cobalt , and 1, *c*),—osmium (1, *i*).
. *Hexagonal Metals.* Arsenic, antimony, tellurium, osmium, iridium, palladium, nuth.
. Sulphur, selenium (1, *b*),—chlorine, iodine, bromine, fluorine, cyanogen, arsenic (?) *c*),—oxygen (1, *e*).
n like manner, the isomorphism of certain groups of elements may be inferred from of compounds in which they may be supposed to exist; thus, from the isomorphism he corresponding phosphates and arsenates, regarded as compounds of metallic oxides, P^2O^5 and As^2O^5, *e. g.* $2Na^2O.H^2O.P^2O^5 + 24H^2O$ and $2Na^2O.H^2O.As^2O^5 + 24H^2O$, isomorphism of phosphoric and arsenic anhydrides may be inferred.
he isomorphism of different elements and groups of elements is, however, most pletely shown by their capability of replacing one another in composition in various

Digitized by Google

proportions, and without any alteration of crystalline form. Thus, in the alums, wh general formula is $MR'''(SO^4)^2.12H^2O$ the monatomic radicle, M, may be composed potassium, sodium, ammonium, &c., and the triatomic radicle, R, of aluminium, ferricu manganicum, chromicum, &c., in the most various proportions, the form, all the whi remaining the same as that of common potash-alum, $KAl(SO^4)^2.12H^2O$. Numberl examples of this isomorphous replacement are found among natural minerals; inde it is but rarely that any mineral is found in which the principal constituents are r more or less replaced by isomorphous substances. Striking examples of it are afford by the spinels (p. 397, and group 1, *g*, Table I, p. 424), and by the garnets (1, *l*, p. 424

Relations between Crystalline Form and Atomic Volume.—Complete isomorphi between two compounds implies the fulfilment of three conditions, viz.:

1. Similar atomic constitution.
2. Similar crystalline form.
3. Equal atomic volumes of the several constituent elements.

By the volume of an atom, we understand, as explained in the article Atom Volume (i. 440), the space occupied by the solid atom itself, together with a porti of the space which separates it from the intervening atoms: that is to say, the size, rather the radius, of the atom (regarded as spherical) is supposed to include half t distance which separates it from the contiguous atoms. The atomic volume of a su stance, according to this definition, is proportional to its atomic weight divided its specific gravity $\frac{a}{s}$. It is clear that equal numbers of atoms similarly disposed w not *necessarily* produce the same external form, unless the corresponding atoms in t two bodies are equal or at least proportional in volume.

Two or more bodies in which all three of the above conditions of equality are f filled, are isomorphous in the stricter sense. The fulfilment or non-fulfilment of all some of these conditions gives rise to eight different cases of similarity or dissimilar of constitution, which may be enumerated as follows:

Crystalline form.	Atomic constitution.	Atomic volume.		
a. equal	equal	equal	Isomorphous in the narrower sense	Isomorphous in the wider sense
			Isotomous	
b. equal	equal	unequal	Homœomorphous	
c. equal	unequal	equal		
d. equal	unequal	unequal		
e. unequal	equal	equal	Heteromorphous	Anisomorphous in the wider sense
f. unequal	equal	unequal		
g. unequal	unequal	equal		
h. unequal	unequal	unequal	Anisomorphous in the narrower sense; Anisotomous	

The following table exhibits the atomic volumes of a number of bodies arrang according to similarity of crystalline form and atomic constitution. The first colun of figures headed $\frac{a}{s}$, gives the quotient of the atomic weight divided by the speci gravity (the atomic weights being those of the oxygen scale, O = 200); the seco gives the atomic volumes referred to that of carbon 44, as unity; the third, head "theoretical," shows what the value of $\frac{a}{s}$ would be in each case if it were an exa multiple of 44.

* Compounds containing indefinite proportions of isomorphous elements are represented in this wo by formulæ in which the isomorphous elements are separated by semicolons: *e.g.* alum, in which t potassium is partly replaced by ammonium, is expressed by the formula, $(K; NH^4)\ Al(SO^4)^2.12H^2$ In many works such compounds are represented by formulæ like $\left.\begin{matrix}K\\NH^4\end{matrix}\right\}Al(SO^4)^2.12H^2O$; but t is objectionable, since, according to ordinary usage, it would imply that the molecule contains an ato of potassium as well as an atom of ammonium, whereas the real meaning is that the potassium a ammonium are present in such quantities as together to make up a monatomic atom or molecule.

this table leads to the following general conclusions.
bracketed together in the table can be regarded as
us; and even among these, there are some whose
of strontium and nitrate of lead (44); magnesio-
monic sulphate (49).

regarded as isomorphous are in reality only homœo-
omic volumes differ considerably. Such is the case
gnesia and manganous oxide; soda and silver-oxide;
manganese-blende and zinc-blende; nitrate of potas-
atomic volumes of these homœomorphous bodies are,
y simple proportions, as in the following examples:—

. 1	Arsenic 3
. 2	Phosphorus . . . 4
. 2	Soda (anhydrous) . . 3
. 3	Silver-oxide . . . 4

us in the free state, are not always so in combination.
, manganese, nickel, &c.; but many copper-salts are
ponding salts of the other metals just mentioned.
e isomorphous in the free state, but by no means in
any bodies are isomorphous in their compounds, but
morphous, in the free state: thus phosphorus and
he free state, but isomorphous in their compounds;
nd antimony, magnesia and manganous oxide, potas-
er-oxide, are homœomorphous in the separate state,

Digitized by Google

but isomorphous in some of their compounds. This apparently paradoxical relatio may arise either from dimorphism—the substances in question crystallising in th free state in a form different from that which they assume in combination—or fro variation of atomic volume. In fact, the atomic volume of a compound is, in nearl all cases, less than the sum of the atomic volumes of its elements in the free state, th condensation being greater as the affinity is stronger. Hence it may happen tha elements whose atomic volumes in the free state are unequal, may assume equa volumes in combination, and therefore yield isomorphous compounds.

4. Bodies of different atomic volume often crystallise in the same form, and ar capable of crystallising together. Gold and silver, whose atomic volumes are nearl as 1 : 2, crystallise together in very variable proportions; so likewise do chloride o sodium, chloride of ammonium, and iodide of potassium, whose atomic volumes are t one another as 3 : 4 : 6. It is only, however, in the monometric system that perfec similarity of crystalline form is exhibited by substances of different atomic volume; i crystals belonging to other systems, difference of atomic volume in bodies of simila atomic constitution, is always accompanied by a slight difference in the magnitude o certain angles, as may be seen by comparing the angles and atomic volumes of th several members of the calcspar and arragonite groups (pp. 427, 430), the obtuse ter minal angles in the former, and the angles $P\infty : P\infty$ in the latter diminishing as th atomic volume increases. This relation between atomic volume and crystalline form is further shown by the observation of Mitscherlich, that the angle of a rhombohedro of calc-spar diminishes when the crystal is heated: for the specific gravity is thereby diminished, and consequently the atomic volume increased.

5. An interesting example of homœomorphism is afforded by nitrate of potassium which is dimorphous, having a rhombohedral form similar to that of calcspar, and a trimetric form like that of arragonite. Its angles in these two forms are as follows:

	Atomic volume.	Terminal angle of rhomb. (nearly).
Hexagonal Nitre KNO^3	27	106° 30′
		∞P $P\infty$
Trimetric Nitre KNO^3. . . .	27	61·0′ 70° 4′

In its rhombohedral form, this substance agrees very nearly with dolomite and dial logite, the terminal angles of which are 106° 15′ and 106° 51′ respectively, and whos atomic volumes are equal to 9: hence it appears that two substances whose atomi volumes are as 1 : 3 may crystallise nearly in the same form. Similar relations though not quite so close, may be traced between the atomic volumes and crystallin forms of rhombic nitre and arragonite.

The relations between the atomic volumes and crystalline forms of different sub stances are, however, far from being established on a perfectly satisfactory basis indeed the general conclusions of different observers relating to this subject are i some instances directly contradictory to each other: the discrepancies doubtless aris in many instances from the want of exact determinations of crystalline form, and mor especially of specific gravity.

Schröder, to whose observations, together with those of Kopp, the results detailed in the preceding pages are mainly due, has recently made further experiments on the relations between chemical constitution and specific gravity, and has arrived at the following conclusions respecting the atomic volumes of isomorphous bodies. When two different elements or groups of elements, *A* and *B*, unite with other elements or groups of elements, *C*, *D*, *E*, &c., forming the compounds *AC* and *BC*, *AD* and *BD*, *AE* and *BE*, &c., belonging to the same type and isomorphous by pairs, the differences of the atomic volumes of *AC* and *BC*, *AD* and *BD*, *AE* and *BE*, &c., are always equal; but if the pairs of compounds thus formed are not isomorphous, or if they are isomorphous, but belong to different types, then the differences of atomic volume are unequal, and different from what they would be if the pairs were isomorphous or belonged to the same type. If bodies of equal atomic volume be denominated isosteric, and analogous pairs of compounds exhibiting equal differences of atomic volume, parallelosteric, the preceding law may be more shortly stated as follows:—*Pairs of compounds which are isomorphous and analogous are likewise parallelosteric.* This law has been confirmed by Tschermak. (Wien. Akad. Ber. xlv. [2] 603.)

Schröder further concludes that the volume of any element, which, in the isomorphous nitrates, chlorides, bromides, iodides or sulphides, is the greater of the two constituting a pair, is condensed in the isomorphous sulphates, carbonates, silicates, and aluminates, to a comparatively greater amount, so as often to become the lesser of the two. Thus the atomic volumes of chloride, bromide, and nitrate of potassium (calculated on the hydrogen-scale) of atomic weights, are greater by 2·7 to 2·5 than those of the corresponding ammonium salts, whereas that of sulphate of ammonium is greater by 2·5 than that of sulphate of potassium.

Digitized by Google

With regard to the elements, Schröder finds that isosterism is accompanied quite as quently, if not more so, by heteromorphism as by isomorphism; but that elements ose atomic volumes are to one another as 1 : 2 (like silver and gold) are often norphous. In oxides and salts also, Schröder finds that isosterism is associated with norphism less frequently than with heteromorphism.

The relations between the atomic volumes and the proportions of the axes (which ermine the angles) in series of homœomorphous bodies, are also, according to röder's recent observations, less constant than was formerly supposed. It is true t the limiting members of each series with regard to the proportions between the s, are also the limiting members with regard to the atomic volumes; but the rmediate terms do not generally exhibit the regular relation between axial propor- s and the atomic volumes which has been noticed in the calcspar and arragonite ups. According to Tschermak, on the contrary (Wien. Akad. Ber. xlv. [2], 603; resber. 1862, p. 9), homœomorphous bodies of analogous composition form the e series with regard to their axial relations, as with respect to their atomic volumes. mpare i. 449–452.)

Polymeric Isomorphism. This term is applied by Scheerer to express the fact 1 at. of an element may in some cases be replaced by two or more atoms of ther, or, generally, m atoms of one element by n atoms of another, or by a group toms of other elements, without essential alteration of crystalline form. Instances his kind of isomorphism are afforded by the sulphides of lead and silver (PbS Ag^{2}S), by the sulphide and chloride of silver (Ag^{2}S and Ag^{2}Cl^2), by numerous norphous chlorides and cyanides, in which the single atom Cl and the group CN harge equivalent functions; and by the isomorphous salts of potassium and ammo- n, in which NH^4 is equivalent to K. Numerous other examples may be found ongst organic compounds: thus the acetate and butyrate of copper, C^{2}H^{3}O^{2}Cu, and ^{7}O^{2}Cu, are isomorphous, and the sulphates of many organic bases, *e. g.* ethylamine, hylamine, conine, unite with sulphate of aluminium, forming alums isomorphous n common potash-alum.

Natural minerals likewise afford examples of this kind of isomorphism, to which ntion has been particularly directed by Scheerer. Thus, certain varieties of ite and hornblende contain alumina, while others, which are free from alumina, tain a larger proportion of silica, the substitution taking place, according to Scheerer, he proportion 1 at. Al^2O^3 to 1 at. SiO^2 (or $3Al^2O^3$ to $2Si^3O^3$), but, according to melsberg, in the ratio of $2Al^2O^3$ to $3SiO^2$ (p. 169). Another instance is afforded the minerals cordierite (dichröite), and aspasiolite, which are isomorphous and e in composition, excepting that, according to Scheerer, 1 at. magnesia in the ner is replaced by 3 at. water in the latter. According to the formulæ given by mmelsberg, however (*Mineralchemie*, pp. 768, 834), viz.,

Cordierite, $6MgO.6(Al; Fe)^2O^3.15SiO^2$.
Aspasiolite, $4MgO.6(Al; Fe)^2O^3.15SiO^2.8H^2O$,

ppears that 4 at. water in the latter take the place of 1 at. magnesia in the former. or a full development of the theory of polymeric isomorphism as applied to minerals, Scheerer (Handw. d. Chem. iv. 170).—On isomorphism in general, see Mitscher- h (Ann. Ch. Phys. [2], xiv. 172; xix. 350; xxiv. 264 and 355).—Breithaupt. J. pr. m. iv. 249).—Persoz, Ann. Ch. Phys. ISONITROPHENIC ACID. See PHENIC ACID.

ISOPHANE. Syn. with FRANKLINITE (ii. 707).

ISOPRENE. C^5H^8.—A very volatile hydrocarbon, polymeric with caoutchin 757), obtained, together with the latter and other less volatile products, by the dry illation of caoutchouc and gutta percha. After repeated rectification over sodium, oils between 37° and 38°, has a specific gravity of 0·6823 at 20°, and vapour- sity = 2·40 obs.; 2·36 calc. After keeping for a month, it became thickened, and uired a bleaching action, in consequence of the absorption of ozone: on subse- ntly distilling it, the ozone acted violently on the hydrocarbon, and the residue denly solidified to a white amorphous mass having the composition $C^{10}H^{16}O$. r. Williams, Proc. Roy. Soc., x. 516.)

ISOPURPURIC ACID. *Picrocyamic acid.* $C^8H^5N^4O^6$. (Hlasiwetz, Ann. Ch. rm. cx. 289; Jahresber. 1860, p. 455. Bayer, Bull. Acad. roy. Belgique, [2] vii. 8.)—An acid, isomeric with purpuric acid, but, like the latter, not known in the free

Digitized by Google

state. The potassium-salt is obtained by the action of cyanide of potassium on pic acid:

$$C^6H^3N^3O^7 + 3CNK + 3H^2O = C^8H^4KN^5O^6 + CO^2 + NH^3 + 2KHO.$$

When a solution of 2 pts. cyanide of potassium (prepared by Liebig's process, 215), in 4 pts. water, warmed to about 60°, is mixed with a solution of 1 pt. pic acid in 9 pts. water, the mixture being constantly stirred, a strong odour of ammo and hydrocyanic acid is given off, and the liquid solidifies on cooling to a soft cryst line pulp; and on straining this mass upon linen, pressing it between bibulous pap heating and triturating the red-brown crystalline residue with a small quantity water, then throwing it on a filter, washing it with cold water, again pressing, d solving it in a large quantity of boiling water, and leaving the hot-filtered solution crystallise, *isopurpurate of potassium* separates, as a metal-green film, and in brown-r crystalline scales, exhibiting a green colour by reflected light. It dissolves sparing in cold, more easily in boiling water, imparting a very deep purple colour, and precipitated from a concentrated solution by carbonate of potassium,—which circu stance may be taken advantage of in the preparation of the salt, if, in consequence the presence of impurities, it does not separate spontaneously as above described. T salt dissolves also in dilute *alcohol*. When heated to about 215°, it decomposes, w somewhat strong detonation, slight appearance of fire, and formation of a grey clou it may also be exploded by contact with sulphuric acid. Its solution is precipitat by salts of barium, lead, mercury, and silver; not by those of calcium, strontiu copper, or zinc. The solution does not give the ordinary reactions of cyanogen.—T salt dried at 100° contains $C^8H^4KN^5O^6$.

The *ammonium-salt*, $C^8H^4(NH^4)N^5O^6$ (at 100°), separates in metallic-shining, da green crystals, on adding a solution of chloride of ammonium to a very concentrat solution of the potassium-salt. It is easily recrystallised, and then forms small wed shaped crystals, brown-red by transmitted and green by reflected light. It is ve slightly soluble in cold water, more easily in boiling water, forming a deep-pur solution. When heated on platinum-foil, it deflagrates like gunpowder.

The *barium-salt*, $C^{16}H^8Ba''N^{10}O^{12}$ (at 100°), separates on adding chloride of bari to a solution of the potassium-salt, as a nearly cinnabar-coloured precipitate, sparin soluble in cold water, perfectly soluble, with purple colour, in hot water. In the state it has a light-green metallic lustre, but when triturated becomes red again, deflagrates with a dazzling green light.

On mixing the hot concentrated solutions of cyanide of barium and picric acid, t liquid acquires a blood-red colour, and deposits a dark-coloured precipitate which resolved by hot water into a red-brown powder with green lustre, soluble in water, a a substance containing a large quantity of carbonate of barium, insoluble therein.

The *calcium-salt*, $C^{16}H^8Ca''N^{10}O^{12}.3H^2O$, separates, after 24 hours, from a mixture a hot-saturated solution of the ammonium-salt with chloride of calcium, in gre metallic-shining needles, which give off their water at 140°.

Lead-salt, $C^{16}H^8Pb''N^{10}O^{12}$.—The solution of the potassium-salt is completely preci tated by neutral acetate of lead; the precipitate, which is at first brown red and ve bulky, soon becomes dark violet-brown and pulverulent; it dissolves with pur colour in boiling water, and the solution deposits slender microscopic needles, whi after drying, are light brown-red with greenish iridescence, and detonate very sharp when heated. It is not completely decomposed by sulphydric acid, and on boiling t remaining mass with water, a yellowish-red solution is obtained, which deposits shini brown crystalline tufts having the composition of the original salt.

The *potassium-salt*, $C^8H^4KN^5O^6$ ($C^8H^2KN^5O^5$, according to Bäyer), has been alrea described.

The *silver-salt*, $C^8H^4AgN^5O^6$ (at 100°), separates from a solution of the potassiu salt, on addition of nitrate of silver, as a brown precipitate, which dries up to a dar green mass possessing metallic lustre. It detonates when heated, and dissolves wi purple colour in a large quantity of boiling water.

The *sodium-salt*, $C^8H^4NaN^5O^6$, is obtained, like the potassium-salt, by the action cyanide of sodium on picric acid. It is dark-green with metallic lustre, dissolves water much more easily than the potassium-salt, and is more difficult to crystallis the solution is red.

The *strontium-salt* is obtained by adding nitrate of strontium to a solution of t potassium-salt, as a green, pulverulent, indistinctly crystalline precipitate, whi deflagrates with a red flame when heated.

Hlasiwetz regards isopurpuric acid as dibasic, and the monometallic salts abo described as acid salts. The neutral salts have not been obtained in definite foru but the solution of the monopotassic salt, mixed with caustic potash, acquires a dar violet colour, and yields a precipitate which soon decomposes and turns brown. similar change of colour, followed by rapid decomposition, is produced on triturati

n-salt with baryta-water. All the salts are very much like the corresponding s; the ammonium-salt, according to Grailich's determinations, exactly re- urpurate of ammonium (*murexid*), in its crystalline form and optical

YRE (from *ἴσος*, equal, and *πῦρ*, fire, because its appearance when fused is as in the natural state). A silicate of calcium, aluminium, and iron, found t, near Penzance, in Cornwall, in a quartzose granite, with tourmalin and tin n breccia, on the Calton Hill, Edinburgh. It bears considerable resemblance n, having a conchoïdal fracture, no cleavage, a greyish-black to velvet-black d vitreous lustre. Specific gravity, 2·912; hardness 6 to 6·5, nearly equal to hoclase. Melts before the blowpipe to a black magnetic globule. Contains, to Turner's analysis (Ed. N. Phil. J. iii. 263), 47·69 silica, 13·91 per cent. 15·43 lime, 20·07 ferric oxide, and 1·94 cupric oxide (loss 1·56 per cent.), early with the formula $Ca^2O.Al^4O^3.3SiO^2$, which is essentially the same as bradorite; but part of the iron in the mineral appears to be in the state of and as long as this amount remains undetermined, the formula cannot be certainty.

ARTARIC ACID and **ISOTARTRIDIC ACIDS.** See TARTARIC IVATIVES OF.

IBROMHYDRIN. Syn. with tribromide of allyl (i. 141).

REBENTHENE. See TURPENTINE.

OLUMITE. A laminated granular quartz-rock, in which diamonds are found: it probably owes its lamination to talc or mica. It occurs in the Brazil and the Ural; also in Georgia and North Carolina, where a few have been found. (Dana, ii. 24.)

ONIC ACID. $C^5H^6O^4$.—An acid obtained, together with citraconic acid y the dry distillation of citric acid. It bears a close resemblance to citraconic differs from it in solubility and in its reactions with nitric acid and with It is prepared by heating citric acid in a retort by a spirit-lamp, care being the heat is applied at the bottom, and not on the sides, as in the latter case would be converted into citraconic acid. The distillation is continued until atic vapours appear. The oily distillate is then dissolved in six parts of ter, and evaporated to crystallisation: the crystals which are first formed itaconic acid; citraconic acid, which is always formed at the same time, issolved in the mother liquor. Frequently the distillate solidifies on cooling. e the crystals are pressed between bibulous paper on a plate at 100°, and then aper moistened with absolute alcohol, and lastly recrystallised from water.

acid is inodorous, and has a strongly acid taste: when crystallised from as the form of a rhombic octahedron. It dissolves in 17 pts. of *water* at 20°, ch more soluble at a higher temperature. It is soluble in *alcohol* and in *ether*. at 161° to a colourless liquid which crystallises on cooling; when further decomposes into citraconic anhydride and water. Unlike citraconic acid, yield mesaconic acid when treated with nitric acid. When treated with nd water, it takes up 2 at. bromine without evolution of hydrobromic acid, an acid having the composition of dibromo-pyrotartaric acid, $C^5H^6Br^2O^4$, Ann. Ch. Pharm. Supp. i. 338; ii. 111; Cahours, Ann. Ch. Phys. [3], , and called *itadibromosuccinic acid* by Kekulé, *dibromitaconic* Cahours (see PYROTARTARIC ACID, DERIVATIVES OF). Citraconic acid yields r an isomeric acid (Cahours). Itaconic acid treated with *sodium-amalgam* at. hydrogen and forms pyrotartaric acid, $C^5H^8O^4$ (Kekulé).

ates. Itaconic acid is dibasic, forming acid salts, $C^5H^5MO^4$, and neutral $^7M^2O^4$. The neutral itaconates of the alkali-metals do not crystallise. The *sium*-salt is very soluble in water, and crystallises in lustrous laminæ. It is y neutralising the acid with potash, adding a quantity of acid equal to that ken, and evaporating to crystallisation. The alkaline salts are soluble, and precipitates with the soluble salts of lead, mercury, and silver.

s of Itaconic acid. The amides of itaconic acid are not known, excepting *aconamic acid*, which appears to be formed by heating itaconate of ammonium hereby a brownish acid mass is obtained which forms a very soluble salt onium. But some of the corresponding phenylamine-compounds have been d by Gottlieb (Ann. Ch. Pharm. lxxvii. 215), to whose researches the eferred for further details.

aconamide, $C^{17}H^{16}N^2O^2$, is derived from neutral citraconate of phenylamine by two atoms of water:

$$C^{17}H^{20}N^2O^4 = 2H^2O + C^{17}H^{16}N^2O^2.$$

Digitized by Google

It is obtained by heating itaconic acid with excess of phenylamine in a retort at a temperature a little above 180°. It crystallises in large thin plates with a pearly lustre.

Phenylitaconamic acid, $C^{11}H^{11}NO^3$, is derived from the acid itaconate of phenylamine by loss of water:

$$C^{11}H^{13}NO^4 - H^2O = C^{11}H^{11}NO^3.$$

It is obtained by evaporating phenylamine to dryness with an excess of itaconic acid, and heating the residue a little above 100°. It forms large colourless needles, more soluble in alcohol than in water. Heated to 160° it is decomposed.

Itaconic Ether. $C^9H^{14}O^4 = C^5H^4(C^2H^5)^2O^4$. Itaconic acid is mixed with alcohol and hydrochloric acid, and the mixture distilled until about a third of the alcohol has passed over: water is then added to the residue, which separates the ether. It is a colourless, inodorous oil with a slight aromatic odour and bitter taste. It boils at 225°, but begins to decompose at this point. E. A.

ITTNERITE. A silicate occurring in monometric crystals, with dodecahedral cleavage, also granularly massive, in the dolerite of the Kaiserstuhl, near Freiberg; in basaltic dolerite at Sasbach; in phonolitic dolerite, with pyrites, titanic iron, and apatite, at Endingen. Hardness = 5·5. Specific gravity = 2·37 to 2·40. Colour dark-bluish or ash grey, or smoky grey. Lustre resinous. Translucent. Fracture imperfectly conchoïdal. When heated in a tube, it gives off a large quantity of water, and before the blowpipe melts easily, with strong intumescence and evolution of sulphurous anhydride, forming a blebby opaque glass. Forms a clear glass with borax. Gelatinises easily with acids.

The composition of the mineral is shown by the following analyses: *a.* by C. Gmelin (Schw. J. xxxvi. 74), *b.* by Whitney (Pogg. Ann. lxx. 442).

	SiO^2	SO^3	Cl	Al^2O^3	Fe^2O^3	CaO	Na^2O	K^2O	Water and loss.*	
a.	34·02	2·86	0·73	28·40	0·61	7·26	12·15	1·56	10·76	= 98·35
b.	35·69	4·62	1·25	29·14	. .	5·64	12·57	1·20	9·83	= 99·94

* Including sulphur undetermined.

According to the latter analysis, ittnerite may be regarded as a mixture of hydrated sodalite and hauyne (p. 15). (Dana, ii. 319; Rammelsberg, *Mineralchemie*, p. 712.)

IWAARITE. A black mineral from Iwaara in Finland, which crystallises in monometric forms, melts before the blowpipe to a black glass, and, according to Thoreld, consists of silica, titanic acid, lime, and ferric oxide: perhaps identical with schorlamite. (Rammelsberg, *Mineralchemie*, p. 887.)

IXIOLITE. A variety of tantalite from Kimito in Finland, containing considerable quantities of manganese and tin.

IXOLITE. A fossil resin found in a bed of bituminous coal at Oberhart, near Glogynitz. It is amorphous, with a fatty lustre and hyacinth-red colour, becoming yellowish when pulverised. It is subtranslucent in thin fragments. Fracture imperfectly conchoïdal in the purer varieties. Specific gravity = 1·008. Hardness = 1. Softens at 76°, but is still tenacious at 100°. (Haidinger, Pogg. Ann. lvi. 345.)

J

JADE. See Nephrite and Saussurite.

JALAP. This name is applied to the roots and tubers of certain plants of the convolvulaceous order, which yield purgative resins. The true or officinal jalap consists of the tubers of *Convolvulus Schiedanus* (or *Exogonia purga*, according to Pereira), which contain a strongly purgative resin called convolvulin, $C^{31}H^{56}O^{16}$ (ii. 15), Kayser's *rhodeoretin*.

Spurious, woody or fusiform jalap, jalap-wood, or jalap-stalks (*Stipites Jalapæ*), the root of *Convolvulus orizabensis*, is sometimes mixed with genuine jalap. Its characteristic principle is jalapin, $C^{34}H^{56}O^{16}$ (Kayser's *pararhodeoretin*, p. 438), a resin homologous with convolvulin, and identical, or nearly so, with scammonin, the active principle of *Convolvulus Scammonia* (p. 438). The experiments of W. Mayer (Ann. Ch. Pharm. xcv. 161) seem to show that both convolvulin and jalapin exist in both kinds of jalap.

JALAPIC ACID. $C^{34}H^{60}O^{18}$? *Scammonic* or *Scammoninic acid.* (W. Mayer, Ann. Ch. Pharm. xcii. 115; xcv. 129. Spirgatis, *ibid.* cxvi. 289.)—An acid produced, with assimilation of water by dissolving jalapin in aqueous solutions of the alkalis or

Digitized by Google

aline earths. Jalapin is heated with baryta-water to the boiling point, until the ole is dissolved, and acids no longer form a precipitate in the solution; the baryta hen removed by sulphuric acid; the excess of this acid by hydrate of lead; and the solved lead, by sulphydric acid. The filtrate boiled to remove the sulphydric acid, l evaporated, deposits jalapic acid, which, in case it has become coloured, may be de-orised by treatment with animal charcoal, or by boiling it with a little hydrate of d, and subsequently passing sulphydric acid through the liquid.

Jalapic acid is a translucent, amorphous, shining, yellowish, brittle mass, which s not soften below 100°, and at about 120° melts to a turbid, very hygroscopic syrup. as no smell, but an irritating sweetish taste (Mayer), or a sourish irritating taste, h bitter after-taste (Spirgatis). It has a strong acid reaction; dissolves very ily in *water*, easily also in *alcohol*, less easily in *ether*. It contains, according to mean of Mayer's analyses, 54·4 per cent. carbon and 8·3 hydrogen; according to irgatis, 54·6 carbon and 8·2 hydrogen: hence Mayer deduces the formula $H^{30}O^{15}$, requiring 54·6 carbon and 7·9 hydrogen; the formula above given, which uires 54·0 carbon and 8·0 hydrogen, is perhaps more probable.

Jalapic acid decomposes at about 130°; when heated on platinum foil, it burns with right sooty flame. When a concentrated aqueous solution is stirred for a long time h fuming *hydrochloric acid*, it splits up into jalapinol and glucose (Mayer):

$$2C^{34}H^{60}O^{18} + 7H^2O = C^{28}H^{48}O^7 + 6C^6H^{12}O^6.$$

e jalapic acid obtained from scammony forms jalapinolic acid, instead of jalapinol irgatis; see p. 440). The same decomposition appears to be caused by emulsin ayer). Mayer obtained alphajalapic acid by boiling jalapic acid with dilute acids *nitric acid* jalapic acid is converted into ipomæic and oxalic acids. When melted h *hydrate of sodium*, it gives off hydrogen, and forms jalapinolic and oxalic acids.

Jalapates. Jalapic acid unites with bases, forming salts in which 1, 2, and 3 at. drogen are replaced by the same number of atoms of metal: mixtures of these ferent salts are, however, very apt to form. It displaces carbonic acid from the car-nates of the alkalis and alkaline earths. Even when neutralised with an alkali, it es no precipitate with any metallic salt, except basic acetate of lead. The jalapates amorphous.

Barium-salts. The *monobarytic salt*, $C^{68}H^{116}Ba^2O^{36}$, is obtained by mixing aqueous apic acid with a slight excess of baryta-water, removing the excess of baryta with bonic acid, then warming and evaporating the filtrate. It resembles the tribarytic t, and contains, according to Mayer's analysis, 49·7 per cent. C, 7·6 H, and 8·6 Ba, above formula requiring 49·4 C, 7·1 H, and 8·3 Ba.

The *tribarytic salt*, $C^{68}H^{114}Ba^3O^{36}$, is prepared by boiling jalapin for 4 to 6 hours, h 2 pts. hydrate of barium and 4 pts. water (or mixing it with an equal weight of drate of barium, melted for half an hour in an air-bath, and then heated with water), l passing carbonic acid through the boiling solution, which is then filtered and porated down, and the residue dried at 100° in a current of air. It is an amorphous, utral, slightly-coloured mass, having a slightly irritating, bitter-sweet taste. It melts 100°, and decomposes with intumescence when strongly heated. It is soluble in ter and alcohol, and is not decomposed by carbonic acid (Mayer, Spirgatis). It ntains, according to Mayer, 42·1 per cent. C, 6·0 H, and 21·6 Ba, the preceding mula requiring 43·2 C, 6·0 H, and 21·8 Ba. [Mayer's formula, $C^{68}H^{116}Ba^3O^{35}$, uires 42·4 C, 5·9 H, and 21·3 Ba.]

A salt of intermediate composition, perhaps the *dibarytic salt*, appears also to be med under certain circumstances (Mayer).

Jalapate of lead.—Recently precipitated hydrate of lead dissolves in boiling aqueous apic acid, forming an amorphous, easily soluble salt. When the aqueous acid is iled for a long time with excess of hydrate of lead, a gummy, tumefied, basic salt is med, which is insoluble in water, and very sparingly soluble in alcohol. The aqueous d gives no precipitate with neutral acetate of lead, but copious white flakes with the sic acetate (Mayer, Spirgatis). Ammoniacal acetate of lead, or the basic acetate, rows down, from the aqueous acid, a flocculent precipitate, which may be purified by eated solution in acetic acid, precipitation with ammonia, and washing. After being ied over oil of vitriol, it does not lose weight at 130° (Keller). It contains, ac-ding to Keller's analysis, 31·1 per cent. lead; the formula $C^{68}H^{114}Pb^3O^{36}$ requires 1 per cent. Keller's salt probably contained excess of base.

Alpha-jalapic acid. $C^{28}H^{50}O^{13}$. (W. Mayer, Ann. Ch. Pharm. xcv. 155.)—ien dilute aqueous jalapic acid is boiled for not too long a time with hydrochloric dilute sulphuric acid, one part of the jalapic acid is completely converted into apinol and sugar, another smaller part into alphajalapic acid, which, on cooling, arates out, with the jalapinol, as a soft, brown, semi-crystalline mass. By boiling s mass with baryta-water, removing the jalapinolate of barium which separates on ling, and concentrating the mother-liquor, white silky needles of alphajalapic acid

Digitized by Google

are obtained, while jalapinate of barium remains in solution. The needles are purified by recrystallisation from water; then dissolved in boiling water, and decomposed by acetic acid; and the alphajalapic acid, which crystallises out on cooling, is collected and purified by washing, recrystallising from water, acidulation with acetic acid, solution in alcohol, and precipitation with hot water.

Alphajalapic acid forms white, flexible needles, exhibiting a silky lustre under water, melting below 80° to a pale yellow thin oil, and forming a crystalline solid on cooling. It has no smell, but an irritating taste, with sweetish after-taste, and is feebly acid. It dissolves sparingly in cold, more freely in boiling *water*, easily in alcohol and in ether.

When the barium-salt (or the acid itself) is *heated*, it is decomposed, with frothing, and gives off a brown acid oil, which solidifies on cooling, partly in the crystalline form. When treated with *dilute acids*, or boiled with *nitric acid*, or melted with *hydrate of potassium*, it exhibits the same reactions as jalapic acid. In the decomposition with dilute acids, however, only 4 at. sugar are formed to 1 at. jalapinol, whereas jalapic acid (p. 437) yields 6 at. sugar:

$$2C^{28}H^{50}O^{13} + 5H^2O = C^{32}H^{62}O^7 + 4C^6H^{12}O^6.$$

Alphajalapate of barium, prepared as above, forms white, glittering, brittle, crystalline needles, having a sweetish irritating taste, and melting easily, without loss of water, to a thin oil, soluble in water and in alcohol. It contains 10·5 per cent. barium, corresponding with the formula $C^{56}H^{98}Ba''O^{26}$, which requires 10·4 per cent. barium.

JALAPIN. $C^{34}H^{56}O^{16}$. (J. Johnston, Phil. Trans. 1840, p. 342; Phil. Mag. [3], xvii. 183.—A. Kayser, Ann. Ch. Pharm. li. 101.—W. Mayer, *ibid.* xcv. 129.—*On Jalapin from scammony-resin:* Johnston, Phil. Trans. 1840, p. 340.—Fr. Keller, Ann. Ch. Pharm. civ. 63; further, with altered data, *ibid.* cix. 209.—Spirgatis, *ibid.* cxvi. 289.)

This substance (Kayser's *Pararhodeoretin*) occurs in the root-stalk of *Convolvulus* (or *Ipomœa*) *orizabensis*, the jalap-stalks or jalap-wood of commerce, and forms the principal portion (soluble in ether) of the jalap-resin prepared therefrom. [On the resin of tuberose jalap-root, see ii. 15.]

The resin of jalap-stalks has been examined also by Hänle (Repert. xlviii. 365), and Planche (J. Pharm. xxiv. 169). According to Weppen (N. Br. Arch. lxxxvii. 153), it resembles the resin of *Convolvulus arvensis*, which, like jalapin, assumes a fine purple-red colour with sulphuric acid, and is soluble in ether (contrary to the statement of Planche, J. Pharm. xiii. 165, who found it insoluble in ether). The same resin has been examined by Chevallier (J. Pharm. ix. 306). The resin of *Convolvulus Soldanella* appears, according to Planche, to be freely soluble in ether and alcohol, as also the portion of the tuberose jalap-root which is soluble in ether: both these resins are therefore, perhaps, jalapin.

Commercial scammony resin, from *Convolvulus Scammonia*, was described some years ago by Bouillon-Lagrange and Vogel; also by Planche (J. Pharm. xiii. 165; xviii. 183). Cl. Marquart (N. Br. Arch. vii. 248; x. 139) described the resin obtained from the root, and believed he had separated from it a vegetable base (*convolvuline*). Johnston recognised the similarity between scammony-resin and the resin of the jalap-stalks; Spirgatis showed that *scammonin*, the chief constituent of the former, is either identical with jalapin, or differs from it only in so far that, when decomposed by acids, it at once yields scammonolic (jalapinolic) acid; whereas jalapin, according to Mayer, when treated in a similar manner, yields at first jalapinol (p. 439). These statements are, perhaps, better founded than the contrary statements of Keller and Kosmann (p. 440.)

According to Planche, the resin of *Convolvulus sepium*, and according to Boutron and Charlard, that of *Conv. Turpethum* (J. Pharm. viii. 131), are not soluble in ether, and may thus be distinguished from jalapin.

In what follows, the statements of Kayser and Mayer relate to jalapin from jalap stalks; those of Keller and Spirgatis, to that from scammony.

Preparation.—a. From commercial *Resina Jalappæ ex stipitibus.* To a solution of the resin in a large quantity of alcohol, water is added, until it becomes slightly turbid; the whole is repeatedly boiled with animal charcoal, and the still-coloured filtrate is precipitated by neutral acetate of lead and a little ammonia, which produces a small greenish-brown precipitate. The liquid is filtered, and the filtrate freed from lead by passing sulphydric acid through it, then heating and filtering; the alcohol is again distilled off, and the resinous residue repeatedly kneaded in boiling water, then dissolved in ether, from which it may be recovered by evaporation (Mayer). Or the alcoholic resin, after treatment with animal charcoal, is boiled for a long time with freshly-precipitated hydrated oxide of lead; the lead is separated from the filtrate by sulphydric acid; and the resin is three times separated by water from the alcoholic solution, then

Digitized by Google

led in water and dissolved in ether (Mayer). Kayser exhausts the root with ; evaporates the tincture; washes the resinous residue with hot water, dissolves cohol, and treats the solution with animal charcoal; distils off the alcohol; e residue again with water; and dries it over a water-bath. Johnston ex- a resin that was obtained either by dissolving the commercial resin in ether porating the solution; or by exhausting the ground root of commerce with hot evaporating the brown tincture, and extracting the residue with ether; or by ng chips of the root with cold alcohol, evaporating, boiling the residue in issolving the resinous residue in ether, and evaporating the solution.

om Scammony.—Coarsely-powdered scammony is exhausted with cold alcohol according to Keller); the tincture is diluted with water till it becomes turbid, sed by animal charcoal, and filtered; the greater part of the alcohol is dis- ; and the residue mixed with water is heated in a water-bath, till the whole lcohol is driven off, after which the resin is treated for a long time in a water- th frequently-renewed hot water, and at last dried up. The residue may be d in ether and recovered by evaporation. (Spirgatis.)

alapin (obtained according to *a* or *b*) still contains a small quantity of a volatile lerianic acid, according to Keller), which cannot be completely removed even long washing. It betrays itself by the smell which the jalapin emits when it rted by bases into jalapic acid, and the resulting solution supersaturated with l acid. Keller regards this acid, the bulk of which passes off in the water washing the jalapin, as an essential product of the decomposition of scammony; Mayer and Spirgatis regard it as a mere contamination.

rties.—Jalapin is a colourless, amorphous resin, translucent when in thin at 100° it becomes brittle, and may be rubbed down to a white powder. It 123°, and melts at 150° to a transparent, colourless, or pale-yellow syrup. It ss and inodorous; in alcoholic solution it gives a scarcely perceptible acid re Mayer, Spirgatis). It is but slightly soluble in *water*, but dissolves very nd without decomposition in *alcohol*, *wood-spirit*, *ether*, and *chloroform*. It also in *benzene*, *oil of turpentine*, and *petroleum*.

mposition of jalapin dried at 100°, or in a vacuum at common temperatures, by the following analyses.

	Calculation.		Analyses.			
			Kayser.	Mayer.	Keller.	Spirgatis.
C . .	408	56·66	58·13	56·52	56·65	56·47
H . .	56	7·77	8·07	8·18	8·39	7·93
O . .	256	35·57	33·80	35·30	34·96	35·60
$^{O^{16}}$	720	100·00	100·00	100·00	100·00	100·00

ton found in the resin obtained from jalap-stalks, 55·76 to 56·65 per cent., in ny-resin 54·06 to 55·32 per cent. carbon. Keller gives the formula $C^{36}H^{57}O^{25}$.

positions.—1. Jalapin *heated* above 127° gives off carbon and hydrogen in n of a volatile compound, which contains less oxygen than the residual resin ton). Jalapin which melts at 150°, becomes brown when further heated, and a pungent empyreumatic odour (Spirgatis).—2. When heated on platinum- kes fire, burns with a bright sooty flame and empyreumatic odour, and leaves .—3. It dissolves slowly in cold strong *sulphuric acid*, the solution, in five or tes, acquiring a beautiful purple or maroon-red colour, then becoming brown, lly black. On standing, or after dilution, a brown resin or a brown tallowy parates from the liquid, while sugar remains dissolved (Kayser, Mayer, tis).—4. By heating with dilute *mineral acids*, jalapin (even that which has solved in alkalis and thereby converted into jalapic acid) is decomposed into and sugar (Mayer). When jalapin from scammony is treated in the same apinolic acid is obtained in place of jalapinol (Spirgatis). Formation of :

$$2C^{34}H^{56}O^{16} + 11H^2O = C^{32}H^{62}O^{7} + 6C^6H^{12}O^6 \text{ (Mayer).}$$

inolic acid:

$$C^{34}H^{56}O^{16} + 5H^2O = C^{16}H^{30}O^{3} + 3C^6H^{12}O^6.$$

alapin (or pure jalapic acid) has been used, no other bodies are produced than st mentioned (Mayer, Spirgatis). According to Keller, when a solution or alcoholic?) of scammonin is treated with strong sulphuric acid or with oric acid gas, and then left to itself, three decomposition-products result, and ation of a fourth (formic acid or formic aldehyde) appears probable from the The products of this decomposition are—*a.* A *neutral body*, $C^{18}H^{30}O^{4}$, also e by alkalis into scammonolic acid (jalapinolic acid), and an alcohol, $C^{28}H^{28}O^{2}$.—

Digitized by Google

b. Amylic aldehyde, which passes over as valerianic acid when scammony-resin is boiled with potash-ley, and then with dilute sulphuric acid.—*c.* A *carbo-hydrate*, $C^{12}H^{9}O^{9}$, which, however, is converted into sugar by simple boiling with dilute sulphuric acid. Keller gives the equation:

$$C^{76}H^{67}O^{35} = C^{28}H^{28}O^{4} + C^{10}H^{10}O^{2} + 3C^{12}H^{9}O^{9} + C^{2}H^{2}O^{2}.$$

But, according to Spirgatis, the neutral body *a* must be regarded as ethyl-scammonolic ether: moreover, the valerianic acid is obtained only from impure scammonin. Kosmann (J. Pharm. [3], xxxviii. 83), by boiling scammony-resin with dilute sulphuric acid, obtains sugar and his *scammoneol*, as a soft, yellowish-white substance, having a silky lustre and acid reaction, and separating from the hot alkaline solution on cooling. He calculates, according to Johnston's analysis of scammony-resin, the formula $C^{32}H^{52}O^{16}$ for scammonin, and so arrives at the equation of decomposition:

$$C^{32}H^{52}O^{16} + 5H^{2}O = 3C^{6}H^{12}O^{6} + C^{14}H^{26}O^{3}.$$

—*5.* When jalapin is dissolved in aqueous solutions of *caustic alkalis*, *ammonia*, or *baryta-water*, or in boiling *alkaline carbonates*, water is assimilated, and jalapic acid, soluble in water, is formed (Mayer, Spirgatis), probably thus:

$$C^{34}H^{56}O^{16} + 2H^{2}O = C^{34}H^{60}O^{18}.$$

Even the purest jalapin yields also traces of jalapinolic acid and a volatile acid, but no sugar (Mayer). When jalapin is melted with *hydrate of sodium*, hydrogen is given off, and jalapinolic and oxalic acids are formed (Mayer). Keller, by boiling scammonin with alcoholic potash, obtained dark flakes (on account of impurities in the scammonin, according to Spirgatis); and on subsequently adding water to the solution, the compound, $C^{26}H^{28}O^{2}$ or $C^{13}H^{28}O$, was precipitated in white flakes, while valerate of potassium remained in solution. The body, $C^{13}H^{28}O$, regarded by Keller as an alcohol, is likewise formed, on boiling commercial jalapin (obtained from the resin of jalap-stalks) or scammony with baryta-water, or solution of potash; it evaporates with the water, and separates in gelatinous flakes from the distillate. At 40° it melts to an oil, crystallises on cooling, and contains, on the average, 78 per cent. C, 14·12 H, and 7·88 O. Keller regards this body as a product of the decomposition of scammonin (or more exactly of the neutral body, $C^{28}H^{28}O^{4}$ or $C^{14}H^{28}O^{2}$; Spirgatis regards it as a mixture of resins, since the greater portion of it is obtained on distilling the impure resin with water.

6. By *nitric acid*, jalapin is at first decomposed into jalapinol and sugar, and these products, when further subjected to the action of the nitric acid, are converted into ipomæic and oxalic acids (Mayer). A small quantity of nitric acid does not colour jalapin; but, in presence of guaiac-resin, a green colour is produced (Bull, Spirgatis). —7. When *sulphurous anhydride* is passed through an ammoniacal alcoholic solution of scammony resin, silvery-shining plates are separated, containing perhaps an aldehyde in combination with acid sulphite of ammonium. (Keller.)

JALAPINOL. $C^{32}H^{62}O^{7}$. (W. Mayer, Ann. Ch. Pharm. xcv. 145.)—Jalapin and jalapic acid are resolved, by contact with mineral acids, slowly at ordinary, more quickly at elevated temperatures, into jalapinol and sugar (pp. 437, 439). Jalapinol and sugar were also produced, in one instance, when aqueous jalapic acid was left for 24 hours in contact with emulsion of almonds at 36° to 38°; whereas, in a second experiment, pure emulsin did not effect the decomposition, perhaps because the solution was too strongly heated.

To prepare jalapinol, a moderately concentrated aqueous solution of jalapic acid is mixed with half its bulk of fuming hydrochloric acid, and left to itself for days, or till the clear mixture has solidified to a thick crystalline pulp; and the product, after being washed on a filter with cold water, is repeatedly melted under warm water, and purified by recrystallisation from alcohol, with help of animal charcoal.

Jalapinol forms white, cauliflower-like crystals, which melt at 62° or 62·5°, and solidify at 59·5° to a hard, brittle, crystalline mass. It makes grease-spots on paper; is inodorous; has an irritating taste, and weak acid reaction. It is soluble in *alcohol* and in *ether*.

In contact with *caustic alkalis*, aqueous *ammonia*, or *baryta*, it is converted, with elimination of water, into a salt of jalapinolic acid:

$$C^{32}H^{62}O^{7} + 2BaHO = 2C^{16}H^{29}BaO^{3} + 3H^{2}O.$$

JALAPINOLIC ACID. $C^{16}H^{30}O^{3}$.—An acid produced—1. By treating jalapinol with caustic alkalis, or with baryta (Mayer).—2. By the action of melting hydrate of potassium on jalapin or jalapic acid (Mayer). Jalapin and jalapic acid, prepared from scammony, are resolved by mineral acids into jalapinolic acid and sugar. (Spirgatis.)

Preparation.—1. Jalapin is added gradually and by small portions to hydrate of

Digitized by Google

melted with $\frac{1}{8}$th pt. of water (the mass then frothing up violently, giving off
gen and turning brown); the mixture is heated and stirred as long as hydrogen
ues to escape; the crumbling light-yellow mass is dissolved in water after cool-
nd the greater part of the alkali is neutralised with acid. The jalapinolate of
, which separates after some hours, is collected, washed, and decomposed by
cidulated water; the separated acid is again repeatedly melted with pure
then dissolved in alcohol and treated with animal charcoal; the somewhat
trated filtrate is mixed with a large quantity of warm water; and the solid acid
separates on cooling is collected (Mayer). From the mother-liquor filtered
he jalapinolate of sodium, excess of acid still separates a small quantity of im-
alapinolic acid (Mayer).—2. The hot aqueous solution of jalapic acid (from
ony) is digested in the water-bath for a fortnight with dilute sulphuric acid;
he tallowy mass which separates on cooling, is freed from sulphuric acid by
g with hot water, and crystallised from ether with help of animal charcoal
gatis).—3. Jalapin from scammony is added to boiling baryta-water; the
is heated till the whole is dissolved, and a sample of the filtrate is not rendered
either by water or by hydrochloric acid; and the solution, after filtration, is
with one-third of its volume of fuming hydrochloric acid. The liquid becomes
in about 20 hours, and solidifies in the course of 10 days to a thick pulp, which
ected, washed with cold water, remelted with hot water, and recrystallised four
times from aqueous alcohol.

perties. Jalapinolic acid forms white tufts of needles, appearing under a magni-
power of 300, as thin 4-sided prisms. It melts at 64° or 64·5° (60° to 61°,
ing to Keller,) and solidifies at 61·5° or 62° (Mayer), at 50° (Spirgatis),
hite radio-crystalline, hard and brittle mass. It makes grease-spots on paper;
ter than water; inodorous, but has an irritating taste and acid reaction (Mayer,
gatis). It is insoluble in *water*, but soluble in *alcohol* and in *ether*.
en *heated* above its melting point, it decomposes with intumescence, emitting a
nt odour which attacks the eyes and throat.—*Nitric acid* oxidises it to ipomæic
nd oxalic acid (Mayer, Spirgatis).

apinolates. The acid is monobasic, the general formula of its neutral salts
$C^{16}H^{29}MO^3$.

pinolate of Ammonium, $C^{16}H^{29}(NH^4)O^3.C^{16}H^{30}O^3$.—By dissolving jalapinol or
olic acid in aqueous ammonia, an opalescent liquid is obtained which gives off
nia when evaporated, solidifies to a crystalline mass when concentrated to a
point, but if completely evaporated, leaves an amorphous neutral jelly soluble
er. The crystals are grouped like cauliflower-heads, and when strongly magni-
ppear as long colourless needles. (Mayer.)

pinolate of Barium, $C^{32}H^{58}Ba''O^6$, is obtained by precipitating jalapinolate of
nium with chloride of barium, or by boiling jalapinol or alcoholic jalapinolic
ith baryta, and crystallises out on cooling, in microscopic, thin, white, lustreless
s, melting to a colourless liquid when heated. It is nearly insoluble in cold,
gly soluble in boiling water, more easily in boiling aqueous alcohol. (Mayer,
gatis.)

pinolate of ammonium precipitates aqueous *chloride of calcium*.

pinolate of Copper. a. *Basic.*—When a slightly alkaline aqueous solution of
monium-salt is precipitated with cupric acetate, and the precipitate is washed
ied at 100°, a dark blue-green, amorphous, very loose mass is obtained, which
without loss of water, to a dark green liquid, and solidifies to a translucent
mass. It is insoluble in water, nearly soluble in alcohol, contains at 100°,
per cent. cupric oxide, and is therefore $2C^{32}H^{58}Cu''O^6.Cu''H^2O^2$ (calc. 18·24 per
CuO). (Mayer.)

Neutral.—$C^{32}H^{58}Cu''O^6$. A hot aqueous solution of jalapinolate of sodium forms
ot aqueous cupric sulphate, a green-blue precipitate, which dries up to a light
reen amorphous powder, melting to a dark green liquid when heated. (Spirgatis.)
e by analysis 13·24 per cent. CuO, the formula requiring 13·28 per cent.

pinolate of ammonium precipitates *iron-salts*.

pinolate of Lead, $C^{32}H^{58}Pb''O^6$, is obtained by precipitating alcoholic jalapinolic
ixed with a little ammonia, with neutral acetate of lead, and washing the white
hous precipitate with dilute alcohol and water. It sinters together to an opaque
t 120°. It is sparingly soluble in water and alcohol.

pinolate of Potassium is obtained by dissolving jalapinol in boiling aqueous
. The solution on cooling solidifies to a crystalline pulp, which, after washing,
crystallisation from water or alcohol, forms slender, white, silky needles, melting
t decomposition when heated. It is neutral, forms an opalescent solution with
even when free alkali is present, and is soluble in alcohol.

pinolate of Silver, $C^{16}H^{29}AgO^3$.—The alcoholic solution of the acid neutralised

Digitized by Google

with ammonia is precipitated by a warm solution of nitrate of silve have a scarcely perceptible crystalline character. (Keller.)

Jalapinolate of Sodium, $C^{16}H^{29}NaO^4$, crystallises in slender da of needles, which form a turbid solution with a small quantity of neutral solution with a larger quantity, and are likewise soluble in alcoh

Jalapinolic Ether, $C^{18}H^{34}O^3 = C^{16}H^{29}(C^2H^5)O^4$. *Scammon* hydrochloric acid gas is passed into a solution of jalapinolic acid in and the resulting liquid is mixed with water, a yellow oil separat washed, after solidification, with cold alcohol, dissolved in boiling al carbonate of sodium, and after it has separated out on cooling, repea from the alcoholic solution by water. It may also be obtained from by passing hydrochloric acid gas into the alcoholic solution. (Spirg

JALPAITE. A cupriferous silver-glance from Jalpa in Me blackish lead-grey colour, is malleable like ordinary silver-glance, a gravity of 6·877 to 6·890. According to an analysis by R. Ri 14·36 per cent. sulphur, 71·51 silver, 13·12 copper, and 0·79 iron, agr the formula, $\frac{3}{4}Ag_2 \atop \frac{1}{8}Cu''$ ^2S. (Breithaupt, Jahresber. 1858, p. 682.)

JAMAÏCINE. An alkaloïd said to be contained in the bark of a leguminous tree growing in Jamaica and in Surinam. (Hüttens Mag. Pharm. Sept. 1824.—Winckler, Pharm. Centr. 1840, p. 120.

JAMESONITE. A sulphantimonite of lead occurring in ∞P : ∞P = 101° 20′ and 78° 40′. Observed planes ∞P, ∞P∞. very distinct; parallel to ∞P and ∞P∞ less distinct. Sometimes capill with columnar structure; particles delicate, straight and parallel or d ness = 2 to 2·5. Specific gravity = 5·5 to 5·8 (Haidinger). Colour and streak steel-grey. Opaque. Sectile.

When heated in an open tube, it gives off dense white fumes of an on charcoal before the blowpipe it decrepitates, fuses readily, and wholly in fumes.

Analyses.—*a.* from Cornwall, mean of three analyses by H. Rose 99).—*b.* from Estremadura, by Schaffgotsch (*ibid.* xxxviii. 403).— by Bechi (Sill. Am. J. [2] xiv. 60).—*d.* from Arany, Idka, by L *Berichte*, i. 62).

	S	Sb	Bi	Pb	Fe	Cu	Zn
a.	22·34	34·29	. .	39·94	2·64	0·18	trace
b.	21·78	32·62	1·05	39·97	3·63	. .	0·42
c.	20·53	32·16	. .	43·38	0·94	1·25	1·74
d.	18·59	33·10	0·22	40·82	2·99	1·78	0·35

These analyses lead to the conclusion that Jamesonite is an isomor sulphantimonite of lead $2PbS.Sb^2S^3$, with the corresponding compound zinc, and silver). Such a mixture of one molecule of the iron-salt an of the lead-salt, viz. $2FeS.Sb^2S^3.3(2PbS.Sb^2S^3)$ or $(FePb^3Sb^6)^{\cdots}S^{16}$, wou per cent. S, 32·55 Sb, 42·02 Pb, and 3·79 Fe.

Jamesonite occurs principally in Cornwall, associated with quartz an of bournonite; occasionally also in Siberia, Hungary, Spain, and Brazi Rammelsberg, p. 68).

JAPONIC ACID. $C^{12}H^{10}O^4$.—An acid produced by exposing tion of catechin in caustic potash. The liquid slowly blackens, and chloric acid, a black precipitate of japonic acid is produced. The a water, but insoluble in alcohol. It forms with potash, a black sal black precipitates with metallic solutions. (Svanberg, Ann. Ch. P

JARGIONITE. A variety of galena, crystallised in octahedrons. 6·932.

JARGON. Syn. with Zircon.

JAROSITE. A native ferroso-potassic sulphate from Baranco J Amagrera in Spain. Crystallises in yellowish rhombohedrons wit (Dana, ii. 389.)

JASPER. A sub-species of quartz of which the following vari rated by Jameson.

1. *Egyptian jasper*, which is red or brown. The first is flesh-red, and brown, in ring-shaped delineations; in roundish pieces, dull, wit ture. Feebly translucent on the edges. Hard; easily frangible. Spec It is found imbedded in red clay-ironstone at Baden, and is cut into o

Digitized by Google

The *brown* variety has its various shades of colour disposed in concentric stripes, ternating with black stripes. It occurs in the sands of Egypt, in spheroïdal masses, ith glimmering lustre. Fracture conchoïdal. Feebly translucent on the edges. As rd as horn-stone. Specific gravity 2·6. Infusible. It is cut into ornaments.

2. *Striped jasper*. Colours grey, green, yellow, red, arranged in stripes, in flamed spotted delineations. Massive, in whole beds. Dull. Fracture conchoïdal. Opaque. ess hard than Egyptian jasper; rather easily frangible. Specific gravity 2·5. It curs in secondary clay-porphyry in the Pentland hills, and near Friburg in Saxony. receives a fine polish.

3. *Porcelain jasper*. Colours grey, blue, yellow, generally of one colour, or with ouded delineations. Massive, and cracked in all directions. Lustre glistening. Frac- re conchoïdal. Opaque. Easily frangible, and not very hard. Specific gravity, 2·5, ses into a white or grey glass. It is always found along with burnt clay and earth ags. According to Werner, it is slate-clay converted into a kind of porcelain, by the eat of a pseudo-volcano from beds of burning coal. It is found on the coast of Fife- ire, in Shropshire, and Warwickshire, and some parts of Germany, where immense eds of coal appear.

4. *Common jasper*. Colours red and brown. Massive. Lustre, from shining to dull. racture conchoïdal. Opaque. Hard in a low degree; rather easily frangible. Specific ravity 2·6. Infusible before the blowpipe, becoming at last white. It occurs princi- ally in veins as a constituent of agate. It is found in the Pentland hills, and in trap nd transition rocks in Ayrshire and Dumfriesshire.

5. *Agate jasper*. Colours yellowish- and reddish-white. Massive, dull. Fracture at, conchoïdal. Opaque. Rather hard. It occurs in layers in agate-balls in many laces. U.

The *iaspis* of the ancients, whence our word jasper is derived, appears to have in- luded the green or blue variety, together with some other stones not of the jasper ind.

JATROPHA. A genus of euphorbiaceous plants, some of which contain in- ensely poisonous juices: the seeds of several species yield fixed oil.

The kernels of the seeds of *Jatropha Curcas* were found by Arnaudon and Ubal- ini (Cimento, vii. 431) to contain 7·2 per cent. water, 37·5 oil, 55·3 sugar, starch, lbumin, casein and inorganic matters. The kernels yielded 4·8 per cent. ash, and ·2 per cent. nitrogen; the kernels and husks together, 6 per cent. ash and 2·9 per cent. itrogen. The oil yielded by saponification, glycerin, and an acid which, as well as he unsaponified oil, produced octylic alcohol by distillation with hydrate of potas- ium.

The oil of the fruit of *Jatropha glauca* and of *J. glandulosa* is yellow, has a specific ravity of 0·963 and solidifies at 5°. (J. Lepine, J. Pharm. [3] xl. 16.)

The root of *Jatropha Manihot* contains a large quantity of starch, which when freed rom the poisonous juice of the plant by washing and torrefaction, constitutes Brazilian rrow-root (i. 359.)

JEFFERSONITE. A dark-green, crystallised, foliated variety of augite, con- aining zinc, from Mine Hill, Franklin, New Jersey. Specific gravity 3·6. Formula Ca; Fe; Mg; Zn)$^{\prime\prime}SiO^3$.

JELLETITE. An altered form of garnet, said to occur in rhombic prisms with ngles of 60°, the supplement of which, 120°, is the angle of the rhombic dodecahedron. pecific gravity = 3·741. Hardness above 7. Occurs as a yellowish, slightly greenish ncrustation, and is compact in its texture. Composition, according to Wright J. Geol. Soc. Dublin, v. 119), 38·09 SiO^2, 33·41 Fe^2O^3, 28·61 CaO = (100·11), which f a small part of the iron is regarded as protoxide, gives the formula of garnet. Dana, ii. 194.)

JEFREINOFFITE or **JEWREINOWITE.** A variety of vesuvian from Finland, containing, according to Ivanhoff, 37·41 SiO^2, 34·20 CaO, 20·00 Al^2O^3, 4·60 FeO, 1·16 K^2O, and 1·70 Na^2O (= 99·07). It is usually yellowish-brown, but some- imes colourless. (Dana, ii. 506.)

JENKINSITE. Syn. with Hydrophite (p. 212).

JERVINE. An alkaloïd discovered by E. Simon (Pogg. Ann. xli. 569), in the oot of white hellebore (*Veratrum album*), in which it exists, together with veratrine. t is extracted by mixing the alcoholic extract of the root with dilute hydrochloric cid and precipitating with carbonate of sodium. The precipitate is dissolved in lcohol, the solution decolorised with charcoal, and the alcohol removed by distillation. The greater part of the residue then solidifies in a crystalline mass, from which the eratrine, being uncrystallisable, may be almost entirely removed by submitting it to ressure, moistening the resulting cake with alcohol, and pressing again. In this

Digitized by Google

manner jervine is obtained nearly pure. A further quantity may be form of sulphate, by evaporating to dryness the expressed liquid, wh jervine and veratrine, and treating the residue with dilute sulphuric up sulphate of veratrine, and leaves sulphate of jervine.

Jervine is colourless and crystalline; gives off 6·9 per cent. water (2 at.) at 100°, and melts at a higher temperature to a colourless poses when heated above 200°. It is insoluble in water, soluble sparingly soluble in ammonia.

According to Will's analysis (Ann. Ch. Pharm. xxxv. 116), it 74·55 per cent. carbon, 9·57—9·74 hydrogen, and 5·38 nitrogen, whe the formula $C^{30}H^{45}N^{2}O^{3}$ for which Gerhardt substituted $C^{26}H^{41}N^{2}$ (calculation 74·7 per cent. C, 9·5 H, 5·7 N, and 10·1 O).

Jervine gives off ammonia when fused with *potash*.

Acetate of jervine is soluble in water. The *sulphate*, *nitrate*, and very sparingly soluble in water and in mineral acids. The *chloropla* yellow flakes which give by analysis 14·55—14·33 per cent. platin $2(C^{30}H^{46}N^{2}O^{3}.HCl).PtCl^{4}$ requiring 14·3 per cent.

JET. A variety of bituminous coal, resembling cannel coal, but a stronger lustre. Specific gravity 1·3. It occurs, together with li floetz, trap, and limestone rocks, and in bituminous shale. It is fou Whitby, in Yorkshire, in the Isles of Skye and Faroe, in Hessia, H and Styria. It is used for fuel and for making various ornamental a

It is the *Gagates* of Dioscorides and Pliny, a name derived from th Syria, near the mouth of which it was found.

JEWREINOWITE. Syn. with Jefreinoffite.

JOHANNITE. Native uranous sulphate. See Uranium.

JOHNITE. Syn. with Turquois.

JUGLANDIN. A substance contained in the juice expressed fr of the walnut (*Juglans regia*). The fresh juice is nearly limpid, h taste, turns brown rapidly in contact with the air, and then loses its prolonged contact with the air, it deposits brown tasteless flocks, i and alcohol, the juice at the same time losing its bitterness. The fr iron-salts; the browned juice, when mixed with potash, precipitates losing its colour at the same time. With nitrate of silver it fo which blackens rapidly, and contains metallic silver.

The extract of green walnut-shells consists of impure juglandin. remedy in cutaneous and scrophulous diseases, also for dyeing the ha *Traité*, iv. 307).

JUNIPER. The berries of the juniper (*Juniperus communis*), w flavouring gin, and in the form of aqueous decoction, also in medi contain, according to Trommsdorff, 1·0 per cent. essential oil of juni resin, 33·8 sugar, together with acetate and malate of calcium, 7·0 g salts, 35·0 woody fibre, and 12·9 water.

The *essential oil of juniper*, obtained by distilling the berries wi composition and vapour-density of oil of turpentine ($C^{10}H^{16}$); boils a plane of polarisation to the left, but less strongly than oil of turpe little soluble in alcohol of ordinary strength. It does not form a sol hydrochloric acid; but after the complete absorption of the gas, a which appears to contain $3C^{10}H^{16}.2HCl$.

The old and moist essence deposits crystals which appear to be iden of turpentine. It is acid and contains formic acid.

By distilling unripe juniper-berries with salt-water, Blanchet obta which boiled at 205°, but appeared to have the same composition as t (*Gerh. Traité*, iii. 637.)

JUNKERITE. Spathic iron ore.

JURINITE. Syn. with Brookite.

K

KÆMMERERITE. A variety of pyrosclerite containing a con of chromium. (See Pyrosclerite.)

KÆMPFERIDE. A substance contained in the root of *Kæ* It may be extracted by ether, together with a brown, viscid, aromati

Digitized by Google

removed by dissolving the product several times in alcohol, the brown sub-
eparating first when the solution is left to evaporate.
pferide crystallises in yellowish nacreous laminæ, without taste or smell. It
t a temperature above 100°, dissolves in 25 pts. of ether at 15°, is less
n alcohol, and nearly insoluble in water. It dissolves in warm acetic acid,
solution yields with ammonia a precipitate soluble in excess of that reagent.
ic acid imparts to it a fine bluish-green colour. Caustic potash dissolves it
low colour; carbonate of potassium with effervescence.
pferide gave by analysis (calculated with the old atomic weight of carbon)
cent. C, 4·3 H and 30·4 O. (Brandes, Ann. Ch. Pharm. xxxii. 312.)

ISACCHARIC ACID. Syn. with GLUCIC ACID (ii. 848.)

YPLOTITE. A name given by Shepard (Sill. Am. J. [2], xii. 210) to
nall black-brown crystals from Haddam, Connecticut, regarded by him as a
eral. Dana, however, regards them as garnets.

IALA. A substance obtained from the fruit of *Rottleria tinctoria*, and used
thelmintic (see ROTTLERIA).

EITE. Arsenical Manganese. (See MANGANESE.)

LIN. The Chinese name of porcelain clay (i. 1024).

NITE. A variety of calamine containing more than 15 per cent. of ferrous
The angle of the rhombohedron R : R is 107° 7 (Breithaupt).

ELINITE. An oxysulphide of bismuth occurring, together with telluric
the Sawodinsk mine in the Altaï. It forms crude lumps, having a metallic
decidedly crystalline fracture, with prevailing cleavage in one direction, strong
lustre on the fractured surface, and lead-grey colour. Hardness = 2; specific
= 6·60. On treating the pulverised mineral with hydrochloric acid, a small
of admixed bismutite (i. 597) dissolves and pure karelinite remains undissolved.
er heated in a test-tube gives off sulphurous anhydride, but no free sulphur,
s a grey slag, from which globules of metallic bismuth ooze out; heated in an
be, it also gives off sulphurous anhydride, and leaves a metallic regulus sur-
by a brown easily fusible oxide. Nitric acid easily decomposes the mineral,
paration of sulphur. The mineral gives by analysis 91·26 per cent. bismuth,
phur, and 5·21 oxygen, agreeing with the formula Bi^4SO^3 or $Bi^2S.Bi^2O^2$.
rmann, J. pr. Chem. lxxv. 448.)

RPHOLITE. See CARPHOLITE (i. 806).

RPHOSIDERITE. See CARPHOSIDERITE (i. 807).

STENITE. Syn. with ANHYDRITE (i. 295).

VA-ROOT. The root of *Piper methysticum* (Forster). When dried be-
10° and 120°, it leaves a residue amounting to 85 per cent.: after exhaustion
ohol and with water, it leaves 75 per cent. of residue containing 26 pts. woody
d 49 starch. By exhausting the root with alcohol of 80 per cent. an extract
a peculiar smell and taste is obtained, the solution of which in warm alcohol
needle-shaped crystals, while a resin remains dissolved.
crystalline substance called methysticin, forms, when purified by repeated
sation, small white silky needles, destitute of taste and smell. It is insoluble
, sparingly soluble in cold alcohol and ether; reacts neutral; melts at 130°, and
ses at a stronger heat; is dissolved by nitric acid with orange-yellow colour,
sulphuric acid with violet colour. It yields by analysis 62·03 per cent carbon,
drogen, and 1·12 nitrogen.
resin kawin, contained, together with myristicin, in the alcoholic extract of
t, is a soft greenish-yellow substance, which has a strong aromatic taste and
melts at 50°, decomposes at a stronger heat, and produces a deep red colour
lphuric acid. 100 pts. of kawa-root contain 15 pts. water, 26 woody fibre,
ch, 1 methysticin, 2 acrid aromatic resin, 3 extractive and gummy matter,
de of potassium, and 3 magnesia, silica, alumina, and ferric oxide. (Gobley.
m. [3], xxxvii. 19.—O'Rorke, Compt. rend. l. 498.)

VAIN. A crystallisable non-azotised substance, from kawa-root; it contain
er cent. carbon and 5·64 hydrogen. (Cuzert, Compt. rend. l. 436; lii. 206.)

WIN. The resin of kawa-root. (See above.)

ORIA TERRESTRIS. Barbadoes tar. (See BITUMEN.)

LHAUITE. Syn. with YTTROTITANITE.

LP. Incinerated sea-weed. (See SEA-WEED.)

RAMOHALITE. A hydrated sulphate of aluminum from near Königsberg

Digitized by Google

in Hungary, having the same composition as alunogen (i. 161). It occurs in crystalline crusts, and six-sided tables of the monoclinic system, with two angles of 92°, and four of 134°. Specific gravity = 1·6 to 1·7. Contains 14·30 per cent. alumina, 2·15 ferrous oxide, 36·75 sulphuric anhydride, 44·60 water, and 2·01 insoluble matter (= 99·81), agreeing approximately with the formula $Al^2(SO^4)^3.18H^2O$.

KERAPHYLLITE. Syn. with CARINTHIN (i. 804).

KERARGYRITE or *Horn-silver*. Native chloride of silver (See SILVER).

KERASITE, *Cerasine*, or *Horn-lead*. A native compound of chloride and carbonate of lead. (See LEAD.)

KERATE. Syn. with KERARGYRITE.

KERMES (*Coccus ilicis*, Lin.) is an insect found in many parts of Asia, and the south of Europe. On account of their figure, these insects were a long time taken for the seeds of the tree on which they live: whence they were called *grains of kermes*. They also bore the name of vermillion.

To dye spun worsted with kermes, it is first boiled for half an hour in water with bran, then for two hours in a fresh bath with one-fifth of Roman alum and one-tenth of tartar, to which *sour water* is commonly added; after which it is taken out, tied up in a linen bag, and carried to a cool place, where it is left some days. To obtain a full colour, as much kermes as equals three-fourths, or even the whole of the weight of the wool, is put into a warm bath, and the wool is put in at the first boiling. As cloth is more dense than wool, either spun or in the fleece, it requires one-fourth less of the salts in the boiling, and of kermes in the bath.

The colour that kermes imparts to wool has much less bloom than the scarlet made with cochineal; whence the latter has generally been preferred, since the art of heightening its colour by means of solution of tin has been known. U.

KERMES, MINERAL. Amorphous trisulphide of antimony. (See ANTIMONY, SULPHIDES OF, i. 330.)

KERMESITE or **KERMESOME.** *Red Antimony. Antimony-blende. Pyrantimonite. Pyrostilbite. Rothspiessglanzerz.*—A native oxysulphide of antimony, occurring in monoclinic crystals, cleaving parallel to the base; usually in tufts of capillary crystals, consisting of elongated, slender, six-sided prisms. Hardness = 1 to 1·5. Specific gravity = 4·5 to 4·6. Lustre, adamantine, inclining to metallic. Colour, cherry-red. Streak, brownish-red. Feebly translucent. Sectile. Thin leaves slightly flexible. Contains 74·45—75·66 antimony, 5·29—4·27 oxygen, and 20·49 sulphur (H. Rose, Pogg. Ann. iii. 453), answering to the formula Sb^2OS^2 or $Sb^2O^3.2Sb^2S^3$. Before the blow-pipe on charcoal, it fuses readily, and is at last entirely volatilised. In nitric acid it becomes covered with a white coating.

This mineral, which results from the alteration of native sulphide of antimony, occurs in veins in quartz, accompanying grey and white antimony, at Malaekza near Posing in Hungary, at Bräunsdoff near Freiberg in Saxony, and at Allemont in Dauphiné. (Dana, ii. 141.)

KEROLITE. See CEROLITE (i. 836).

KETONES. See ACETONES (i. 31).

KHAYA. The bark of the *Caïl-cedra* (*Khaya senegalensis* or *Swietenia senegalensis*), used in Senegal as a remedy against fever, contains a bitter principle, cailcedrin, together with green fat, red and yellow colouring matter, gum, starch, a waxy substance, woody fibre, sulphate and phosphate of calcium, and chloride of potassium. Caïl-cedrin, which may be extracted from the concentrated aqueous extract of the bark by chloroform, is a resinous mass containing 64·9 per cent. carbon, 7·6 hydrogen, and 27·5 oxygen. (Caventou, J. Pharm. [3] xvi. 355; xxxiii. 123.)

KIBDELOPHANE or *Axotomous Iron ore.* A variety of titaniferous iron, occurring sometimes in crystals, but usually massive, or in thin plates or laminæ. R : R = 85° 19′. Hardness = 5 to 5·5. Specific gravity = 4·661 (Mohs); 4·723 to 4·735. (Breithaupt.)

KIFFEKILL. See MEERSCHAUM.

KIESERITE. A name applied by Reichardt (Arch. Pharm. [2], ciii. 346) to a sulphate of magnesium, occurring in the shaft of the Stassfurth salt-mine near Magdeburg, and containing, according to his analysis, 21·66 per cent. MgO, 43·05 SO^3, and 34·56 water (= 99·27), agreeing approximately with the formula $2MgSO^4.3H^2O$.—Siewert (Zeitschr. f. d. ges. Naturw. xvii. 49) found in a much harder opaque specimen (mean) 28·56 MgO, 58·94 SO^3, and 13·47 H^2O), together with from 0·26 to 0·66 of matter insoluble in nitric acid), answering to the formula $2MgSO^4.H^2O$. Similar results were obtained by B. Leopold (*ibid.* p. 51), who also

Digitized by Google

at the salt contained from 0·5 to 1·2 per cent. of an insoluble borate (see s); also previously by Rammelsberg (*Mineralchemie*, p. 264).

RICKENITE. Geocronite from Kilbricken, Clare County, Ireland. (See ITE, ii. 831.)

AS. The Cornish miners' name for clay-slate.

INITE. A mineral having the appearance of spodumene, found at Kil-, near Dublin. According to Mallet, it affords by cleavage a prism of 135°, very nearly the angle between the diagonal and prismatic cleavages of spo- both of which are perfect. Hardness = 4. Specific gravity = 2·56. Lustre, weak. Colour, greenish-grey, brownish, or yellowish. It has been analysed nt, Blythe, Mallet, and Galbraith (Dana, ii. 170; Rammelsberg's *hemie*, p. 837.)

Al^2O^3	FeO	CaO	MgO	MnO	K^2O	Li^2O	H^2O		
30·60	2·27	0·68	1·08	—	6·72	—	10·00	= 100·43	Lehunt.
31·64	2·33	0·72	0·46	1·25	6·06	—	10·00	= 99·80	Blythe.
33·24	3·27	1·45	—	—	4·94	0·46 Na^2O	3·67	= 99·92	Mallet.
30·13	3·53	—	1·09	—	4·81	0·95 Li^2O	7·58	= 98·54	Galbraith.
29·37	2·23	0·34	1·03	—	6·71	0·60	8·03	= 98·42	„

ing to Rammelsberg, this mineral, and likewise pinite, gieseckite, gigan- rite, and liebenerite, which are of somewhat similar constitution, are not ompounds, but products of decomposition intermediate between an original nd mica, which often adheres to and partly penetrates their mass.

C ACID. Syn. with QUINIC ACID.

. This name is applied to four different drugs, bearing considerable resem- catechu, and consisting of dry brown lumps or grains, having a more or less t taste. Their aqueous extracts form green precipitates with ferric salts. varieties of kino are African kino, also called *Gummi gambiense*, or *ia*, from the *Pterocarpus erinaceus* (Lam.); Asiatic kino, from *Pterocarpus m*; New Holland kino, from *Eucalyptus resinifera* (white); and American n *Coccoloba uvifera* (L.).

ing to Vauquelin, African kino consists of 75 pts. tannin and peculiar ex- natter, 24 pts. red gum, and 1 pt. fibrin.

s used in medicine as an astringent like catechu. (Handw. d. Chem. iv. 352.)

ONE. Syn. with QUINONE.

OVOUS ACID. $C^{24}H^{28}O^5$ (?). An acid obtained, together with several ducts, from the needles of *Pinus sylvestris*. (For the mode of preparation, see INS.) It is a white or slightly yellow brittle mass, converted by trituration ongly electric powder. The silver-salt contains 74·1 per cent. oxide of silver nearly with the formula $5Ag^2O.C^{24}H^{28}O^5$. (Kawalier, Wien. Akad. Ber.

IGITE. A name applied by H. Fischer to the mixture of red garnet, mica, elinic felspar (oligoclase), which occurs in veins in primitive gneiss rocks, Vittichen in the Kinzigthal, Scharzwald, at Auerbach in the Bergstrasse, and alities, and is regarded by him as an original formation. (Jahrb. Min., 1860, 861, p. 641.)

A fossil resin, found, with others, on the island of Tschelekän, in the Caspian in other neighbouring localities.

VANITE. A hydrated silicate of aluminium, calcium, and iron, occurring in the Mourne Mountain on the north-east coast of Ireland, in opaque, olive- diating fibres, having a specific gravity = 2·941 and hardness = 2. According alysis by R. D. Thomson, it contains 40·5 per cent. silica, 23·91 ferrous oxide, ne, 11·41 alumina, and 4·35 water (= 99·95), whence Rammelsberg deduces ula: $2[3(CaO.FeO).2SiO^2].Al^2O^3.2SiO^2.2H^2O$; it is possible, however, that part n may be in the state of ferric oxide.

ineral blackens and fuses partially before the blow-pipe, and forms a brown h soda or borax.

PROTHIN. Syn. with LAZULITE.

OCLASE. Syn. with ABICHITE.

BELITE. A mineral of unknown locality, closely related in composition to t differing from it considerably in its properties. According to Döbereiner's (Schw. J. xxi. 49), it contains about 32·5 per cent. silica, 32·0 ferrous oxide, manganous oxide, agreeing nearly with the formula $(Mn'' ; Fe'')^3SiO^4$, or

Digitized by Google

$2(MnO; FeO).SiO^2$.—It is massive, with an uneven and cellular surface, and quite hard. Specific gravity, 3·714. Brittle, with imperfectly conchoïdal fracture. Colour, white to greyish-green, or brown-red and brown. Lustre glistening.

KOBELLITE. A mineral found in the cobalt mine of Hvena in Sweden. It consists, according to Setterberg's analysis (*Berzelius Jahresber.* xx. 215), of 17·86 sulphur, 9·24 antimony, 27·05 bismuth, 40·12 lead, 2·96 iron, 0·80 copper, and 1·45 matrix (=99·48), numbers which may be approximately represented by the formula: $2\left[\begin{matrix}Pb^3\\Sb^2\end{matrix}\right\}S^6] \cdot 3\left[\begin{matrix}Pb^3\\Bi^2\end{matrix}\right\}S^6]$, or $(Pb^{15}Sb^4Bi^6)S^{30}$, the lead being partly replaced by iron and copper. It resembles grey antimony, but has a brighter lustre and radiated structure. Specific gravity, 6·29—6·32. Soft; of blackish lead-grey to steel-grey colour, with black streak. Dissolves in strong hydrochloric acid, with evolution of sulphydric acid. (Dana, ii. 82; Rammelsberg, *Mineralchemie*, p. 106.)

KOENIGITE. Syn. with Brochantite (i. 664).

KOENLITE. A fossil resin resembling scheererite, found in brown coal at Uznach, at Redwitz in Bavaria, and in the Fichtelgebirge. It contains, according to Schrötter's analysis (Pogg. Ann. lix. 37), 92·43 per cent. C, and 7·71 H, agreeing with the formula nCH. It occurs in soft white crystalline folia and grains, of specific gravity 0·88; melts at 114° (Kraus, Pogg. Ann. xliii. 141), at 107·5° (Trommsdorff, Ann. Ch. Pharm. xxi. 126). Very slightly soluble in cold alcohol, more so in hot alcohol, still more in ether.

KOENLINITE. A fossil resin from the brown coal of Fassa, in the Eger Valley. It occurs in thin plates, consisting of an aggregate of crystalline scales, perfectly soluble in alcohol and ether, also in strong sulphuric acid; partly soluble in ammonia and in oil of turpentine. (Kenngott, *Mineralogische Untersuchungen*, ii. 111.)

KOETTIGITE. Native arsenate of zinc, $Zn''(AsO^3)^2.8H^2O$, or $ZnO.As^2O^5.8H^2O$, containing also nickel and cobalt, with a trace of lime.

As^2O^5	ZnO	CoO	NiO	H^2O		
37·17	30·52	6·91	2·00	23·40	=	100

according to Naumann, and isomorphous with cobalt-bloom. Massive or in crusts, with crystalline surface and fibrous structure. Cleavage perfect in one direction. Specific gravity = 3·1. Hardness = 2·5 – 3. Lustre of fracture-surface, silky. Colour, light carmine-red and peach-blossom red, of different shades. Streak, reddish-white. Translucent to subtransparent. (Köttig. J. pr. Chem. xlviii. 183; Naumann, *ibid.* 256.—Dana, ii. 418.)

KOKSCHAROWITE. A crystalline mineral occurring with ultramarine, and sometimes intergrown with it. It exhibits two very distinct directions of cleavage, inclined at an angle of 124°. Hardness = 5 to 5·5. It is sometimes colourless, with a strong lustre, sometimes brown and less lustrous. When heated, it becomes darker in colour, and easily melts to a white semitransparent glass (Nordenskiöld Jahresber. 1857, p. 681).—A specimen from the Slüdänka valley, near Lake Baikal, was found by R. Hermann (Jahresber. 1862, p. 726) to contain 45·99 per cent. silica, 18·20 alumina, 2·40 ferrous oxide, 12·78 lime, 16·45 magnesia, 1·06 potash, 1·53 soda, and 0·60 matter lost by ignition (=99·01). Specific gravity = 2·97.

KORITE. See Palagonite.

KOUMISS. A vinous liquid, which the Tartars make by fermenting mare's milk. A somewhat similar beverage is prepared in Orkney and Shetland.

KOUPHOLITE. Syn. with Prehnite.

KRABLITE. Syn. with Baulite (i. 520).

KRAMERIC ACID. An acid said by Peschier (J. Pharm. vi. 34; x. 348) to exist in rhatany root (*Krameria triandra*). It is crystalline, has a sour and astringent taste, and is not volatile. Its alkaline salts are crystallisable, and their solutions form a white precipitate with lead-salts, yellow with ferric salts. The barium-salt is said not to be decomposed by sulphuric acid or soluble sulphates.

Other chemists who have looked for this acid in rhatany root have not been able to find it.

KRANTZITE. A variety of retinite from the lignite of Latterf, near Bernburg. (See Retinite).

KRAURITE. Syn. with Dufrenite.

KREITTONITE. Syn. with Spinel.

KREMERSITE. Ruby-coloured octahedral chloride of potassium, from Vesuvius. Contains 55·15 per cent. chlorine, 16·89 iron, 12·07 potassium, 0·16 sodium, 15·56 ammonia and water. (Kremers, Pogg. Ann. lxxxiv. 79.)

Digitized by Google

UVIGITE. Brochantite, from **Krisuvig in Iceland.**

KOÏTE. Syn. with CROCOÏSITE (ii. 109.)

RAPHITE. Syn. with TYROLITE.

METHINE. Syn. with CYAMETHINE (ii. 188).

NETHINE. Syn. with CYANETHINE (ii. 189).

NITE or *Cyanite.* A silicate of aluminium, $Al^2O^3.SiO^2$, occurring in triclinic
P. $\infty\breve{P}\infty$. $\infty\breve{P}\infty$. $\infty'P$. $\infty P'$. $2\breve{P}\infty$. Crystals usually bladed. Angles oP : $\infty\breve{P}\infty$
'; oP : $\infty\breve{P}\infty = 100° 50'$; oP : $\infty'P = 98° 58'$; oP : $\infty P' = 96° 42'$; $\infty\breve{P}\infty$:

e occurs principally in gneiss and mica-slate. Transparent crystals are found
thard, in Switzerland; at Greiner and Pfitsch, in the Tyrol: also in Styria,
, and Bohemia; at Pontivy, in France; and at Villa Rica, in South America.
also in many localities in the United States: the specimens analysed by
d Brush were from Monro County, New York.
e (i. 499), from Bamle, in Norway, and xenolite (*q. v.*), have nearly the same
on as kyanite. Woerthite, from near St. Petersburg, containing 40·6 per
², 58·50 Al^2O^3, 1·00 MgO and 4·63 water, and Thomson's hydrobucholzite
from Sardinia), which contains 41·35 SiO^2, 49·53 Al^2O^3, 4·85 water and 3·12
re probably hydrous kyanites. Kyanite has also been observed altered to talc
te. (Dana, ii. 265.)

NOL. Syn. with PHENYLAMINE.

ATIN. Syn. with HORNBLENDE.

PHENINE or **CYAPHENINE.** $(C^{21}H^{15})'''N^3$.—A compound polymeric
ide of phenyl (benzonitrile), C^7H^5N, obtained by heating pulverised cyanate
um with chloride of benzoyl:

$$3C^7H^5OCl + 3CNKO = C^{21}H^{15}N^3 + 3KCl + 3CO^2.$$

hard neutral substance, exhibiting a crystalline fracture; melts at 224°, and
hout alteration at or a little above 350°; is soluble in water, slightly soluble
and ether. When heated with caustic potash, it decomposes, with copious
of ammonia. Sulphuric acid dissolves it, forming an acid whose barium-salt
in water. Strong hydrochloric acid does not dissolve it, even at the boiling
tric acid of ordinary strength is also without action upon it; but fuming
dissolves it, with great rise of temperature, but without evolution of gas;
raporating the solution or mixing it with water, nearly the whole of the
e is precipitated in the form of a nitro-compound, $C^{21}H^{12}(NO^2)^3N^3$, which
s in needles.

ATIN. Syn. with HORNBLENDE.

KYNURENIC ACID. (Liebig, Ann. Ch. Pharm. lxxxvi. 125; cviii. 354.)—An acid sometimes deposited from the urine of dogs. From the urine of a dog whic had been fed on fat alone, or on fat mixed with a small portion of meat, Liebig obtaine it by evaporating, adding hydrochloric acid and leaving the liquid to stand for som time; the urine of dogs fed exclusively on lean meat yielded only traces. The deposi dissolves in lime-water, and on diluting the solution with water, and adding hydro chloric acid, kynurenic acid is deposited in very slender, colourless needles; from con centrated solutions, as a powder.

Kynurenic acid reddens litmus; when heated in a glass tube, it melts to a brow liquid, which then sublimes completely, forming a white silky crystalline sublimat and leaving a trace of charcoal. The precipitated acid is insoluble in alcohol and i ether; the sublimed acid dissolves in alcohol. It dissolves easily in boiling hydro chloric acid (whereby it is distinguished from uric acid), and in dilute sulphuric an nitric acids (in the latter without perceptible alteration, even on boiling). Cold con centrated sulphuric acid dissolves it without alteration; but on heating the solution, i turns brown, and, on addition of water, deposits a lemon-yellow, amorphous precipi tate, often mixed with crystals of the unaltered acid.

Kynurenic acid is a very weak acid. It dissolves easily in caustic alkalis, and, wit aid of heat, in alkaline carbonates, lime-water and baryta-water, neutralising the base and forming crystallisable salts. The *barium-salt* forms plumose groups of nacreou needles; the *calcium-salt*, stellate groups of short hard needles. Both salts are spar ingly soluble in water.

The acid is precipitated from the solution of the barium-salt by carbonic acid. I gave by analysis 61·6 to 61·9 per cent. carbon, 4·7 to 4·4 hydrogen, and 8·7 to 9· nitrogen. When heated alone or with lime, it yields a volatile oil, having the odou of benzonitrile.

KYPHOLITE. Syn. with SERPENTINE.

KYROSITE. White iron pyrites from the mine Briccius, near Annaberg.

L.

LABDANUM or **LADANUM.** A resin which exudes in drops from the leave and branches of the *Cistus creticus* and *C. cyprius*, shrubs growing in Greece an Turkey. It is generally black, solid, tenacious, and somewhat moist; softens betwee the fingers, and exhales an odour like that of ambergris. A sample analysed b Guibourt (*Histoire des Drogues*, iii. 601) contained 86 per cent. resin and volatile oi 7 wax, 1 aqueous extract, and 6 earthy matter and hairs. Commercial labdanum i often largely adulterated with black sand. According to Johnston, labdanum-resi contains 73·2 per cent. carbon and 10·0 hydrogen; a composition which may be approx mately represented by the formula $C^{20}H^{30}O^3$ (calc. 75·5 C, 9·4 H, and 15·1 O).

Labdanum in sticks is prepared in Portugal, Spain, and the South of France, b boiling the leaves and branches of *Cistus ladaniferus*.

LABRADORITE. *Labrador Felspar. Anhydrous Scolecite. Mauilite. Sil cite. Scolexerose.*—A mineral species belonging to the felspar group, and represente by the formula $M^2O.Al^2O^3.3SiO^2$, or $\left.\begin{matrix}(Si^2)^{xii}\\(Al^2)^{vi}\\M^2\end{matrix}\right\}O^{10}$, where M denotes calcium and sodium and occasionally also magnesium and potassium.

Labradorite occurs in triclinic crystals, in which oP : $\infty\breve{P}\infty$ = 86° 32′; oP : ∞' = 114° 48′; $\infty\breve{P}\infty$: $\infty P'$ = 119° 16′. It forms twins like those of albite (ii. 621 Cleavage perfect parallel to oP; distinct parallel to $\infty\breve{P}\infty$, in which direction also th faces are usually striated; indistinct parallel to $\infty P'$. Also massive, with distinc cleavage. Hardness = 6. Specific gravity = 2·67 to 2·76. Lustre of oP pearly passing into vitreous; elsewhere vitreous or subresinous. Colour usually grey, o various shades; also greenish, reddish, or yellowish. Some varieties, especially thos from Labrador, exhibit a beautiful play of colours when viewed in certain directions this effect is best seen in cut and polished specimens. Streak uncoloured. Fractur glistening. Translucent in a low degree. Less easily frangible than commo felspar.

Before the blowpipe on charcoal it fuses, with less difficulty than orthoclase, to colourless glass. With oxide of nickel and borax it forms a blue bead. When pul verised, it is entirely dissolved by hydrochloric acid, which does not attack eithe orthoclase or albite.

umber of molecules of lime be supposed to be three times as great as that of he above formula, which then becomes $\left.\begin{matrix}\frac{3}{4}Ca''\\ \frac{1}{2}Na\end{matrix}\right\}O.Al^2O^3.3SiO^2$, gives 53·1 per 30·1 Al^2O^3, 12·3 CaO, and 4·5 Na^2O.

orite is more subject to alteration than other felspars; perhaps because it oth potash and soda. Partial decomposition is shown, either by the dimi- antity of these bases, or by the consequently increased proportion of silica. examples of unaltered labradorite in the preceding table are perhaps *e*, *f*, *g*, *k* and *l*, if the analyses are correct, afford decided indications of decomposi- numerous analyses of labradorite, and of felspars allied to it, see *Rammels- neralchemie*, pp. 597—603.

orite is a constituent of some lavas, as those of Etna and Vesuvius; of many s, as the oriental *verd antique* of Greece; of dolerite; of certain hornblende- nites, and syenites; of some porphyritic greenstones, as at Campsie in Scot- melaphyres, as in the Tyrol. On the coast of Labrador, whence it was brought, it is associated with hornblende, hypersthene, and magnetic iron na, ii. 238.)

RNIC ACID. An acid said to be contained, together with cytisine (ii. 311) neutral bitter principles, in the seeds, bark, and other parts of *Cytisus* . (T. Scott Gray, Arch. Pharm. [3] xlii. 160.)

s a substance well known in Europe under the different appellations of stick- lac, and seed-lac. The first is the lac in its natural state, encrusting small or twigs. Seed-lac is the stick-lac separated from the twigs, appearing in a l form, and probably deprived of part of its colouring matter by boiling. is the substance which has undergone a simple purification, as mentioned Beside these we sometimes meet with a fourth, called lump-lac, which is the nelted and formed into cakes.

he product of the *Coccus laccæ*, which deposits its eggs on the branches of a l Bihar, in Assam, and other parts of India. It appears designed to answer se of defending the eggs from injury, and affording food for the maggot in a anced state. It is formed into cells, finished with as much art and regularity ycomb, but differently arranged; and the inhabitants collect it twice a year, nths of February and August. For purification, it is broken into small pieces, nto a canvas bag of about four feet long, and not above six inches in circum- Two of these bags are in constant use, each of them being held by two men. is placed over a fire, and frequently turned, till the lac is liquid enough to ugh its pores; then taken off the fire, twisted in different directions, and at time dragged along the convex part of a plantain tree prepared for this pur- l while this is being done, the other bag is being heated, to be afterwards

Digitized by Google

treated in the same way. The mucilaginous and smooth surface of the plantain tree prevents it from adhering; and the degree of pressure regulates the thickness of the coating of lac, at the same time that the fineness of the bag determines its clearness and transparency.

Stick-lac contains in 100 parts, resin 68, colouring extract 10, wax 6, gluten 5·5, extraneous substances 6·5; seed-lac contains resin 88·5, colouring extract 2·5, wax 4·5, gluten 2; shell-lac contains resin 90·9, colouring extract 0·5, wax 4, nitrogenous matter 2·8. (Hatchett.)

In India, lac is fashioned into rings, beads, and other trinkets; sealing-wax, varnishes, and lakes for painters, are made from it; it is much used as a red dye, and the resinous part, melted and mixed with about thrice its weight of finely-powdered sand, forms polishing stones. Lapidaries mix powder of corundum with it in a similar manner.

The colouring matter is soluble in water; but 1 pt. of borax to 5 of lac renders the whole soluble by digestion in water, nearly at a boiling heat. This solution is equal, for many purposes, to spirit varnish, and is an excellent vehicle for water-colours, as, when once dried, water has no effect upon it. Aqueous potash, soda, and carbonate of soda, likewise dissolve it; so does nitric acid, if digested with it in sufficient quantity for 48 hours.

The colouring matter of lac loses much of its beauty by keeping; but when freshly extracted, and precipitated as a lake, it is less liable to injury. Mr. Stephens, a surgeon in Bengal, sent home a large quantity precipitated in this way with alum; it afforded a good scarlet to cloth previously yellowed with quercitron.

Lac is the basis of the best sealing-wax. A good composition for red sealing-wax is 48 pts. of shellac, 12 oil of turpentine, 1 Peru balsam, and 36 vermillion. U.

LAC-DYE. A product obtained from lac, and used for producing a red dye, especially on wool. To obtain it, stick-lac freed from remains of stalks is pulverised and exhausted with warm water; and the colouring matter left on evaporating the solution is made into square cakes, and sent into the market as lac-dye. The residue yields seed-lac (*Lac in granis*), which is worked up into shell-lac. The proximate constitution of lac-dye is not exactly known; it contains, however, a considerable quantity of resin, and a red colouring matter, derived from the insects (*Coccus laccæ*), which may be partly extracted by water, more completely by acids, especially sulphuric or hydrochloric acid. The following processes are adopted for rendering the dye fit for use:

1. A mixture of 4 pts. lac with strong sulphuric acid is allowed to stand for 24 hours in summer and 48 in winter; then diluted and stirred with 3½ pts. of water, and again left to clarify. The clear liquid is poured into an iron pot, and mixed with the wash-water of the previous residue; the solution is mixed with a quantity of lime sufficient to neutralise $\frac{4}{5}$ of the sulphuric acid, and the precipitate of gypsum is removed: the liquid is then ready for use. This is the mode of preparation chiefly adopted in this country.

2. Thirty-two pts. of lac-dye are triturated with 10 to 12 pts. of sulphuric acid of specific gravity 1·85, or hydrochloric acid of specific gravity 1·13, each diluted with three times its weight of water. The mixture is left to itself for 48 hours in winter, or 24 in summer, and then mixed with the requisite quantity of river-water.

3. Thirty-two pts. of lac-dye are triturated with 12 pts. of hydrochloric acid of specific gravity 1·148, diluted with an equal weight of water; the mixture is left for 24 hours and frequently stirred, and then diluted with water.

To dye with the colour thus prepared, each pound is mixed with three-quarters of a pint of so-called lac-spirit, a solution of stannous chloride prepared by dissolving one pound of tin in 20 pounds of fuming hydrochloric acid, the mixture being left to itself for six hours before use. (Handw. d. Chem. iv. 748. See also *Ure's Dictionary of Arts, &c.* ii. 626.)

LACTAMETHANE. *Ethyl-lactamide*, $C^3H^{11}NO^2 = \begin{matrix} C^2H^5 \\ (C^3H^4O)'' \\ H^2 \end{matrix} \Big\} \begin{matrix} O \\ \\ N \end{matrix}$. (Wurtz, Ann. Ch. Phys. [3] lix. 175.)—This compound is formed when diethylic lactate is treated with aqueous ammonia, and the mixture is left to stand for one or two days; or when an alcoholic solution of the ether is saturated with ammonia and heated in a close vessel. The former process is, according to Wurtz, to be preferred. After expelling the excess of ammonia and water by evaporation in the water-bath, the lactamethane remains as a liquid, which solidifies on cooling to a beautiful crystalline mass, formed of broad, brilliant plates, slightly greasy to the touch. These crystals are soluble in water, alcohol, and ether; they melt at 62° or 63° to a colourless liquid, and boil at 219° under a barometric pressure of 761 mm., distilling without alteration.

The formation of lactamethane may be represented by the equation

$$\begin{matrix} C^2H^5 \\ (C^3H^4O)'' \\ C^2H^5 \end{matrix} \Big\} O + NH^3 = \begin{matrix} C^2H^5 \\ (C^3H^4O)'' \\ H^2 \end{matrix} \Big\} N + C^2H^6O.$$

Diethylic lactate. Lactamethane. Alcohol.

Digitized by Google

By ebullition with potash, it is decomposed into ammonia and ethyl-lactate of potassium:

$$\underset{\text{Lactamethane.}}{\begin{matrix}C^2H^3\\(C^3H^4O)''\\H^2\end{matrix}\Big\}\begin{matrix}O\\N\end{matrix}} + KHO = \underset{\text{Ethyl-lactate of potassium.}}{\begin{matrix}C^2H^5\\(C^3H^4O)''\\K\end{matrix}\Big\}\begin{matrix}O\\O\end{matrix}} + NH^3.$$

G. C. F.

LACTAMIC ACID. Syn. with ALANINE (i. 63). It is also produced by the action of very strong solution of ammonia on chloropropionate of ethyl at 100°. (Kolbe, Ann. Ch. Pharm. cxiii. 220.)

Lactamate of ammonium (so called), $C^6H^{14}N^2O^4 = \begin{matrix}H^2\\(C^3H^4O)''\\(C^3H^4O)''\\H^4N\end{matrix}\Big\}\begin{matrix}N\\O.\\O\end{matrix}$—Formed by the action of ammonia-gas on lactic anhydride (DILACTIC ACID, p. 461) (Pelouze); or by saturating a solution of lactic anhydride in absolute alcohol with dry ammonia, and evaporating the solution. Tabular crystals, very easily soluble in water and alcohol. On adding dichloride of platinum to the solution, freed by boiling from excess of ammonia, only part of the nitrogen is precipitated as chloroplatinate of ammonium; but after boiling the filtrate for an hour, it gives a further precipitate with dichloride of platinum—a proof that part only of the nitrogen exists in the form of ammonium-salt. (Laurent, Compt. chim. 1845, p. 151.) G. C. F.

LACTAMIDE. $C^3H^7NO^2 = \begin{matrix}H\\(C^3H^4O)''\\H^2\end{matrix}\Big\}\begin{matrix}O\\N\end{matrix}$. (Isomeric with alanine or lactamic acid (i. 63), $C^3H^7NO^2 = \begin{matrix}H^2\\(C^3H^4O)''\\H\end{matrix}\Big\}\begin{matrix}N\\O\end{matrix}$.)—Obtained—1. By the action of ammonia gas on lactide (Pelouze; Wurtz and Friedel, Ann. Ch. Phys. [3] lxiii. 108).—2. By the action of an alcoholic solution of ammonia on lactide (Wurtz and Friedel, *loc. cit.*).—3. By saturating monethylic lactate with ammonia and leaving the liquid to stand. (Brüning, Ann. Ch. Pharm. civ. 197.)

It forms small prisms, which dissolve easily in *water* and *alcohol*, but do not combine either with acids or bases. It is decomposed, by boiling with alkalis or acids, into ammonia and lactic acid.

The above formula represents lactamide as derived from the double molecule $\begin{matrix}H^2O\\H^2N\end{matrix}\Big\}$ by the substitution of the radicle C^3H^4O for H^2. The substances described under the names lactamethane (p. 452), and lactethylamide (*vid. inf.*), are ethylised derivatives of lactamide; the former by the substitution of C^2H^3 for the hydrogen-atom of the water-residue contained in lactamide, the latter by the substitution of C^2H^5 for one of the hydrogen atoms of the ammonia-residue. These relations are expressed in the rational formulæ by which lactamethane, lactethylamide, and lactamide are respectively represented at the places referred to. G. C. F.

LACTETHYLAMIDE. $C^5H^{11}NO^2 = \begin{matrix}H\\(C^3H^4O)''\\C^2H^5.H\end{matrix}\Big\}\begin{matrix}O\\N\end{matrix}$. Isomeric with lactamethane (Wurtz and Friedel, Ann. Ch. Phys. [3] lxiii. 110). Formed by the action of ethylamine on lactide. When these two substances are brought together, the ethylamine immediately begins to boil. If the operation is performed in a close vessel, and with anhydrous materials, the whole solidifies to a crystalline mass. This product, when purified by one crystallisation from alcohol, melts at 48°, and may be cooled to 40° without freezing; but as soon as crystallisation has commenced, the thermometer rises to 46·5°. Lactethylamide distils without alteration at 260°. Its formation is represented by the equation

$$\underset{\text{Lactide.}}{C^6H^4O^2} + \underset{\text{Ethylamine.}}{C^2H^7N} = \underset{\text{Lactethylamide.}}{C^5H^{11}NO^2}.$$

Alkalis decompose it into ethylamine and alkaline lactate.

$$\underset{\text{Lactethylamide.}}{\begin{matrix}H\\(C^3H^4O)''\\C^2H^5.H\end{matrix}\Big\}\begin{matrix}O\\N\end{matrix}} + KHO = \underset{\text{Lactate of potassium.}}{\begin{matrix}H\\(C^3H^4O)''\\K\end{matrix}\Big\}\begin{matrix}O\\O\end{matrix}} + \underset{\text{Ethylamine.}}{C^2H^5.H^2N}.$$

G. C. F.

LACTIC ACID. *Milchsäure*, $C^3H^6O^3 = \begin{matrix}(C^3H^4O)''\\H^2\end{matrix}\Big\}O^2$. (Gm. xi. 472).—This acid was discovered by Scheele in sour milk, and first recognised as a peculiar acid by Berzelius. Braconnot found in the wash-liquor of the preparation of wheat-starch, in the fermented juice of mangold-wurzel, and other fermented vegetable extracts,

Digitized by Google

an acid which he designated *nanceic acid*, but which was afterwards shown to be identical with the acid of sour milk. Berzelius demonstrated the presence of the same or an isomeric acid in the juice of the flesh of animals recently killed—a result which was confirmed by Liebig in his classical investigation of flesh-juice (see SARCOLACTIC ACID, p. 457). More recently, the chemical relations of lactic acid have been investigated by Strecker (Ann. Ch. Pharm. lxxxi. 247; xci. 352), Wurtz (Ann. Ch. Phys. [3] lix. 161), Wurtz and Friedel (*ibid.* lxiii. 101), and Kolbe (Chem. Soc. Qu. J. xii. 15); and the lactates have been chiefly studied by Pelouze (Ann. Ch. Phys. [3] xiii. 257), and by Engelhardt and Maddrell (Ann. Ch. Pharm. lxii. 83; lxx. 241).

Formation.—1. By a peculiar fermentation, the *lactic acid fermentation*, of various kinds of sugar, and of dextrin: this fermentation precedes the butyric acid fermentation. As all the substances of the sugar tribe have the same proportional composition as lactic acid, with a few atoms of water more or less, the transformation is easily explained: thus, with milk-sugar:

$$\underset{\text{Milk-sugar.}}{C^{12}H^{20}O^{10}} + 2H^2O = \underset{\text{Lactic acid.}}{4C^3H^6O^3}$$

The lactic fermentation requires a temperature between 20° and 40° C., and the presence of water and of certain ferments, viz., albuminoïdal substances in a peculiar state of decomposition, such as casein, gluten, or animal membranes, particularly the coating of the stomach of the calf (rennet), or dog, and bladder.

2. Tritylglycol, in presence of platinum-black, is converted into lactic acid by the oxygen of the air (Wurtz):

$$\underset{\text{Tritylglycol.}}{C^3H^8O^2} + O^2 = \underset{\text{Lactic acid.}}{C^3H^6O^3} + H^2O$$

3. Chloropropionic acid yields chloride of silver and lactic acid, when it is heated with water and oxide of silver. (Wurtz, Ann. Ch. Phys. [3] lix. 165):

$$\underset{\substack{\text{Chloropropionate of}\\ \text{silver.}}}{C^3H^4ClAgO^2} + H^2O = \underset{\text{Lactic acid.}}{C^3H^6O^3} + AgCl$$

Similarly, bromopropionic acid yields lactic acid and bromide of silver, when treated with oxide of silver in presence of water (Friedel and Machuca, Ann. Ch. Pharm. cxx. 286). Iodopropionic acid (formed by the action of iodide of phosphorus on glyceric acid) appears to yield a peculiar modification of lactic acid when treated as above. (Beilstein, *ibid.* p. 234.)

4. By the action of nitrous acid upon alanine; as when the vapours evolved from a mixture of starch and nitric acid, after being passed through a cold vessel which stops any undecomposed nitric acid, are conducted into aqueous alanine; the action is attended with copious evolution of nitrogen:

$$\underset{\text{Alanine.}}{C^3H^7NO^2} + \underset{\text{Nitrous acid.}}{NO^2H} = \underset{\text{Lactic acid.}}{C^3H^6O^3} + H^2O + N^2$$

5. Pyruvic (pyroracemic) acid, treated in aqueous solution with sodium-amalgam (Wislicenus, Ann. Ch. Pharm. cxxvi. 227), or with zinc in presence of dilute acetic acid (Debus, Chem. Soc. J. xvi. 260), is converted into a salt of lactic acid:

$$\underset{\text{Pyruvic acid.}}{C^3H^4O^3} + H^2 = \underset{\text{Lactic acid.}}{C^3H^6O^3}$$

6. When hydroxycyanide of ethylene, $\left.\begin{matrix}(C^2H^4)''\\ H\end{matrix}\right\}\begin{matrix}CN\\ O\end{matrix}$ (obtained from hydroxychloride of ethylene by double decomposition with cyanide of potassium), is boiled with aqueous alkalis, it is resolved into ammonia and (sarco-) lactic acid. (Wislicenus, Ann. Ch. Pharm. cxxviii. 6):

$$\underset{\substack{\text{Hydroxycyanide}\\ \text{of ethylene.}}}{C^3H^5NO} + 2H^2O = \underset{\text{Lactic acid.}}{C^3H^6O^3} + H^3N$$

Ethyloxycyanide of ethylidene, $\left.\begin{matrix}(C^2H^4)''\\ C^2H^5\end{matrix}\right\}\begin{matrix}CN\\ O\end{matrix}$ (obtained by digesting ethyloxychloride of ethylidene [ii. 600] with cyanide of potassium in a sealed tube), yields ordinary lactic acid, and a small quantity of ethyl-lactic acid, when similarly treated. (Wislicenus, *op. cit.* p. 14.)

7. Oxychloride of carbon combines directly with ethylene, forming chloride of lactyl:

$$COCl^2 + C^2H^4 = C^3H^4OCl^2,$$

whence lactic acid can be obtained by well-known processes. (Lippmann, Ann. Ch. Pharm. cxxix. 81; Ann. Ch. Phys. [4] i. 485.)

Preparation.—a. *From various kinds of Sugar.*—1. An aqueous solution of 100 pts. of grape-sugar (cane- or milk-sugar), exhibiting the density of 8° to 10° Bm., is mixed

Digitized by Google

with 8 or 10 pts. of fresh sour cheese, as purchased in the market, or 100 pts. of sugar are dissolved in 100 to 150 pts. of milk, and such a quantity of water that the liquid exhibits a density of 10° Bm.; and either of these mixtures is placed, together with 50 pts. of chalk, in an open vessel, and exposed to the sun for several weeks, with frequent agitation, till the resulting lactate of calcium begins to change into butyrate (Pelouze and Gelis). As lactate of calcium is much less soluble than butyrate, the conversion of the former into the latter may be recognised, when strong solutions of sugar are used, by the diminution of the crystalline mass produced at first. If the process be too soon interrupted, a large quantity of sugar remains unaltered.

2. Six pounds of cane-sugar and half an ounce of tartaric acid (which serves to convert the cane-sugar into glucose) are dissolved in 26 pounds of boiling water; 3 pounds of levigated chalk added after two days, together with 4 ounces of stinking hand-cheese, suspended in 8 pounds of sour milk (decaying cheese favours the production of lactic acid and retards its conversion into butyric acid); the mixture set aside at a temperature between 30° and 35°, and well stirred every day till, in the course of six or eight days, it is converted into a stiff paste of lactate of calcium; this paste is boiled for an hour with half an ounce of quicklime and 20 pounds of water; the solution strained through a cloth filter and evaporated to a syrup; the crystalline mass which forms in four days, pressed, first by itself, then three or four times, after having been each time stirred up, with $\frac{1}{10}$ pt. of cold water; and the lactate of calcium thus purified is dissolved in twice its weight of boiling water. To the solution of every 32 pts. of the calcium-salt there is then added a mixture of 7 pts. oil of vitriol and 7 pts. water; the lactic acid, while still hot, is strained through linen to separate it from sulphate of lime; the filtrate obtained from 7 pts. of oil of vitriol is boiled with $1\frac{3}{4}$ pts. carbonate of zinc for a quarter of an hour (by longer boiling a very sparingly soluble basic salt is formed); the liquid is filtered boiling hot; the colourless crystalline grains of lactate of zinc which separate on cooling, are freed from sulphuric acid by washing with cold water; and additional quantities of crystalline grains are obtained by evaporating the mother-liquor, almost to the end. Lastly, 1 pt. of the zinc-salt is dissolved in $7\frac{1}{2}$ pts. of boiling water; sulphuretted hydrogen passed through the solution as long as sulphide of zinc is precipitated; and the filtrate boiled and evaporated on the water-bath to a syrup, whereupon 8 pts. of the zinc-salt yield 5 pts. of syrupy lactic acid (Bensch, Ann. Ch. Pharm. lxi. 174). By this process, 100 pts. of cane-sugar yield 117 pts. of lactate of calcium, which, if the sugar was white, is colourless, and does not require to be purified by pressure. If the carbonate of zinc contains lime and magnesia, these bases pass over to the lactic acid, which, after being evaporated to a syrup, must be dissolved in ether, and separated from the lactates of calcium and magnesium by filtration and evaporation. The calcium-salt may, however, without first preparing the zinc-salt from it, be freed by repeated crystallisation from a nitrogenous substance which obstinately adheres to it; its solution in the smallest possible quantity of water, mixed with a quantity of pure sulphuric acid not quite sufficient to decompose it; the mixture heated with alcohol till the sulphate of calcium is completely separated; the filtrate evaporated to a syrup; the syrup dissolved in ether; and the ethereal solution filtered and evaporated. (Engelhardt and Maddrell.)

Lautemann (Ann. Ch. Pharm. cxiii. 242) recommends the following modification of Bensch's process of preparation:—Retaining the proportions of sugar, tartaric acid, milk, and cheese indicated by the latter, he takes one-third more water, uses 1,200 grms. oxide of zinc (commercial zinc-white) instead of levigated chalk, and keeps the temperature as constantly as possible between 40° and 45° during the fermentation. After eight or ten days, the inside of the vessel is lined with white crystals of lactate of zinc, which can be obtained pure by one or two crystallisations from boiling water. The lactic acid prepared from the zinc-salt generally contains mannite, which does not completely crystallise out from the concentrated acid. To separate this, the aqueous acid is shaken up with ether, and then the ethereal layer is pipetted off and evaporated: it then leaves pure lactic acid.

3. The solution of 300 grms. of milk-sugar in 4 litres of milk is placed in the open air at a temperature of 25° to 30°, and neutralised with acid carbonate of sodium as often as it becomes sour, perhaps every two days; boiled when it no longer turns acid; filtered from the curd; carefully evaporated to a syrup; and the syrup dissolved in moderately warm alcohol of 38° Bm. By treating this filtered alcoholic solution of lactate of sodium with sulphuric acid to precipitate the sodium, and saturating the filtered lactic acid with chalk, crystallised lactate of calcium is obtained, and may be purified by further treatment. (Boutron and Frémy, J. Pharm. xxvii. 341.)

b. *From milk which has turned sour.*—1. Scheele evaporates sour whey to $\frac{1}{8}$; filters the liquid from the curd; precipitates the phosphoric acid from it with lime; filters; dilutes with 3 pts. water; precipitates the lime by careful addition of oxalic acid; filters; evaporates to the consistence of honey; extracts the lactic acid with alcohol;

Digitized by Google

filters; dilutes with water, and evaporates. Berzelius digests the acid thus obtained with carbonate of lead; filters; precipitates the dissolved lead with sulphydric acid, filters, and evaporates.—2. The filtered solution of sour whey evaporated nearly to dryness, in strong alcohol, is mixed with alcoholic tartaric acid, as long as any precipitate of tartrate of potassium, sodium, and calcium is formed; the liquid decanted after 24 hours, and evaporated; the residue dissolved in water; the solution digested with carbonate of lead, till lead dissolves in it; the filtrate evaporated, neutralised with carbonate of barium, again filtered, and diluted with water; the whole of the barium precipitated with sulphate of zinc; and the filtrate evaporated till lactate of zinc crystallises out (Berzelius, Lehrb. Ausg. 5, v. 241. For the earlier methods of Berzelius, see Pogg. Ann. xix. 26). W. Engelhardt (Zeitschr. Chem. Pharm. 1861, p. 643) gives the following process for the preparation of lactate of zinc, from which he then obtains lactic acid by decomposing the hot solution of the zinc-salt with sulphydric acid, filtering and evaporating. Sour whey, to which $\frac{1}{20}$ of its weight of powdered milk-sugar has been added, is exposed to the proper temperature for the lactous fermentation, and every one or two days the free acid is neutralised with crushed carbonate of sodium taken from a previously weighed quantity. When at last the acid reaction does not reappear after two or three days, the liquid is heated to boiling, and sulphuric acid is added, drop by drop, so as to produce a distinct acid reaction. A quantity of sulphate of zinc equal in weight to the carbonate of sodium used is then dissolved in twice its own weight of water, and mixed with the other boiling liquid; the cheesy portions which immediately separate at the surface are removed by filtration through flannel-bag and the clear liquid is set aside to crystallise. After a day or two, the crystalline deposit of lactate of zinc may be removed and washed with cold water. The quantity remaining in the mother-liquor is insignificant. (For Cap and O. Henry's process, see J. Pharm. xxv. 138; also Ann. Ch. Pharm. xxx. 106.)

Properties.—Lactic acid is a colourless liquid of syrupy consistence, and specific gravity 1·215 at 20·5° C. It is inodorous, but has an intensely sour taste. It absorbs moisture from the air; dissolves in all proportions in water and alcohol, somewhat less freely in ether. It does not solidify at −24° C.

Decompositions.—1. *Dry distillation.* The acid, when very gradually heated, becomes less viscid; gives off at 130°, slowly and without evolution of gas, colourless water, together with a small quantity of lactic acid, and leaves a pale yellow, solid, easily fusible, extremely bitter residue of *lactic anhydride* (dilactic acid), $C^6H^{10}O^5 = 2C^3H^6O^3 - H^2O$. This residue remains unaltered up to 250°, but from 250° to 300°, at which temperature the decomposition is complete, gives off carbonic oxide gas, mixed at first with 4 or 5, and at last with 50 per cent. of its volume of carbonic anhydride (altogether a quantity of gas amounting to 33·1 per cent. of the lactic anhydride), and yields a distillate amounting to 90 per cent. of the anhydride, and consisting of *lactide*, $C^6H^8O^4 = 2C^3H^6O^3 - 2H^2O$ (p. 464), which crystallises out on cooling and likewise sublimes, of *lactone* (p 464), with small quantities of acetone, and an odoriferous oil insoluble in water, whilst a quantity of difficultly combustible charcoal remains, amounting to 6·9 per cent. of the anhydride (Pelouze). The anhydride, which remains undecomposed after heating to 240°, gives off, when kept for some time between 250° and 260°, carbonic oxide mixed with 3 or 4 per cent. of its bulk of carbonic anhydride (without any carburetted hydrogen); yields a yellowish distillate, which deposits crystals of lactide, and contains, in addition to the lactide (amounting to 14·9 per cent. of the anhydride), nothing but ordinary lactic acid, citraconic acid, aldehyde (amounting to 12·2 per cent. of the anhydride), but neither acetone nor lactone; and leaves 1 or 2 per cent. of shining, easily combustible charcoal. The aldehyde and the citraconic acid [?] are perhaps merely products of decomposition of the lactide, $C^6H^8O^4 = 2C^2H^4O + 2CO$. The ordinary lactic acid is formed from a portion of the anhydride by addition of the water set free by the conversion of the remainder into lactide. If the anhydride be distilled at 300° instead of 260°, less lactic acid and lactide are obtained, and more aldehyde (Engelhardt). Lactic acid, when heated, gives off pungent vapours which excite coughing, and yields a brown empyreumatic oil, together with an acid liquid, the acid of which is neither lactic nor acetic acid, but forms a viscid uncrystallisable salt with oxide of zinc (Braconnot, Ann. Ch. Phys. l. 375). It yields a watery distillate continually becoming more acid, the first portion of which, however, assumes a syrupy consistence when evaporated *in vacuo*, and if then gently heated in contact with the air, deposits crystals of lactide; it afterwards yields an oil and then a buttery mass, which solidifies in the neck of the retort, and when exhausted with cold ether, leaves scales and ultimately rhombic laminæ. Lastly, there remains a shining, tumefied charcoal. The acid which remains after partial distillation likewise contains a certain quantity of lactide; and on boiling this acid with ether and cooling the liquid, the lactide crystallises out (Corriol). By continued heating to between 180° and 200°, the acid is much more quickly converted into the anhydride, and yields a much more copious distillate of the unaltered acid, than between 130° and 140°;

Digitized by Google

and if a platinum wire be immersed in the liquid, the lactic acid may be distilled over quite unaltered, and with regular ebullition (Engelhardt). If the lactic acid contains a small quantity of sulphuric acid, it yields only carbonic oxide gas, no carbonic anhydride (Pelouze). If it contains the smallest quantity of impurity, albumen for example, it does not yield any sublimate of lactide (Gay-Lussac and Pelouze). Lactic acid, heated slowly in contact with the air, boils gently, emitting a suffocating odour, swells up, blackens, and leaves a spongy charcoal. (Berzelius.)

2. Lactic acid (or ferrous lactate), mixed with a sixfold quantity of *oil of vitriol*, and gently heated, froths up briskly, acquires a dark-brown colour; gives off about $\frac{1}{4}$ of its weight of pure carbonic oxide gas; and at a higher temperature, yields about $\frac{1}{4}$ of its weight of a humus-like substance. (Pelouze.)

3. Boiling *nitric acid* converts lactic into oxalic acid. (Jules Gay-Lussac and Pelouze.)

4. Lactic acid and its salts, distilled with small quantities of *common salt, peroxide of manganese, sulphuric acid*, and water, yield chiefly aldehyde; with larger quantities, principally chloral. (Städeler, Ann. Ch. Pharm. lxix. 332.)

5. With aqueous *alkaline hypochlorites*, or *chlorous acid*, lactic acid is converted, first into oxalic acid, then, with effervescence, into carbonic anhydride. (Cap and Henry.)

6. When treated with *peroxide of barium* or of *lead*, it is converted chiefly into oxalic acid. (Cap and Henry.)

7. Distilled with *dilute sulphuric acid* and *peroxide of manganese* or *peroxide of lead*, it yields a large quantity of aldehyde, together with carbonic anhydride. (Liebig.)

8. Lactate of calcium distilled with *pentachlorides of phosphorus*, yields chloride of lactyl $(C^3H^4O)''.Cl^2$:

$$\left.\begin{matrix}C^3H^4O\\H^2\end{matrix}\right\}O^2 + PCl^5 = C^3H^4OCl^2 + PCl^3O + H^2O.$$

9. *Hydriodic acid*, or a mixture of di-iodide of phosphorus with a small quantity of water, reduces lactic acid to propionic acid:

$$\underset{\text{Lactic acid.}}{C^3H^6O^3} + 2H^2 = \underset{\text{Propionic acid.}}{C^3H^6O^2} + H^2O.$$

(Lautemann, Ann. Ch. Pharm. cxiii. 217.)

10. The action of *fuming sulphuric acid* upon lactic acid or lactate of calcium produces di-sulphometholic acid. (Strecker, Ann. Ch. Pharm. cxviii. 291.)

Sarcolactic or **Paralactic Acid.** In 1806, Berzelius discovered an acid in muscular flesh which he believed to be identical with the lactic acid prepared from milk. In 1847, Liebig (Ann. Ch. Pharm. lxii. 278 and 326) showed that this acid, though similar to the acid of sour milk in composition and in many other respects, nevertheless exhibited distinct differences from it in some of its salts. He therefore distinguished it by the name Sarcolactic acid (*Fleischmilchsäure*), in place of which Paralactic acid was proposed by Heintz (Pogg. Ann. lxxv. 391). In 1858, it was found by Strecker (Ann. Ch. Pharm. cv. 313) that, by heating paralactic acid for a long time to 130° or 140° and dissolving the resulting lactic anhydride in water, this acid may be transformed into ordinary lactic acid.

Preparation.—Chopped flesh is exhausted with cold water or dilute alcohol; the infusion is mixed with baryta-water; the albumin is coagulated by boiling, and removed by filtration; and the clear liquid is concentrated by evaporation Sulphuric acid is added to the syrupy residue, and it is shaken with ether, which then leaves paralactic acid when evaporated.

The difference between sarcolactic and ordinary lactic acids is most distinctly marked in their calcium- and zinc-salts (see below, Lactate of calcium and Lactate of zinc): the acids themselves are hardly to be distinguished.

Thebolactic acid. This is another modification of lactic acid found, by T. and H. Smith, of Edinburgh, in the mother-liquors of the preparation of morphine. Some of its salts are said to differ in certain respects from ordinary lactic acid (see Thebolactic acid).

Lactates. The best known salts of lactic acid are of the form $C^3H^5MO^3$: there are also acid salts containing $C^3H^5MO^3.C^3H^6O^3$, and double salts, $C^3H^5MO^3.C^3H^5M'O^3$. The existence of these acid and double salts led Gerhardt and other chemists to double the formula of lactic acid, making it $C^6H^{10}O^6$, and regarding the neutral salts as $C^6H^{10}M^2O^6$, and the acid salts as $C^6H^{11}MO^3$. But the relations between lactic and propionic acids have induced chemists in general to return to the lower formula of lactic acid, and to regard the acid lactates as constituted like the acid acetate of potassium (i. 17). Moreover, Wurtz's discovery of the diethylic lactate would render it necessary to regard the acid with the higher formula as tetrabasic, for which there is no warrant.

The crystalline lactates do not effloresce on exposure to the air, but give off water *in vacuo*, and the whole of it at 100°, excepting the acid nickel-salt which retains it till heated to 130°. They sustain a heat of 150° to 170° without decomposition; the

Digitized by Google

zinc-salt may be heated even to 200°. They are for the most part sparingly soluble i cold water, and effloresce rapidly from their solutions: they are all insoluble in ethe

LACTATE OF AMMONIUM.—Obtained by neutralising the acid with ammonia. Form prismatic crystals which deliquesce and give off ammonia when exposed to the air.

LACTATE OF ANTIMONY.—Oxide of antimony dissolves in lactic acid or in aci lactate of potassium, but does not form a crystalline salt.

LACTATE OF BARIUM.—The *neutral* salt is uncrystallisable and very soluble i water. The *acid salt*, $Ba''(C^3H^5O^3)^2.2C^3H^6O^3$, is obtained by adding to a solution of th neutral salt a quantity of lactic acid equal to that which it already contains. It i then deposited in crystals which may be purified by washing with alcohol. It is n altered by exposure to the air or *in vacuo*. It dissolves easily in water. Gives off a aromatic odour at 100°.

LACTATE OF BISMUTH.—Only two basic salts are known: α. $2Bi'''(C^3H^5O^3)^3.Bi^2O$ This salt is obtained in needles by treating hydrate or carbonate of bismuth wit lactic acid, and evaporating. A better mode of preparing it is to mix the concentrate solutions of nitrate of bismuth and lactate of sodium—the latter in slight excess, whereb a crystalline pulp is precipitated consisting of lactate of bismuth mixed with nitr On redissolving this in a small quantity of water, and leaving the solution at rest, th lactate of bismuth is deposited in crystalline crusts.

β. $Bi'''(C^3H^5O^3)^3.2Bi^2O^3$.—By proceeding in the manner just described, but wit boiling solutions, or by adding nitrate of bismuth drop by drop to a solution of lactat of sodium, the salt β is precipitated as a powder unalterable in boiling water. I appears also to be produced by the solution of α.

LACTATE OF CADMIUM, $Cd''(C^3H^5O^3)^2$.—Obtained in small needles by dissolvin carbonate of cadmium in the acid. When deposited from a boiling solution, it i anhydrous. Insoluble in alcohol.

LACTATES OF CALCIUM.—The *neutral acetate*, $Ca''(C^3H^5O^3)^2.4H^2O$ and $Ca''(C^3H^5O^3)$ $5H^2O$, is obtained by saturating a boiling solution of lactic acid with carbonate c calcium, and evaporating the filtered liquid. It is also produced abundantly when solution of sugar mixed with cheese and carbonate of calcium is left to itself for som weeks at a temperature of 20° to 30° C. According to Corriol, the same salt is de posited from an infusion of *nux vomica* which has fermented for a few days. It is de posited from an aqueous or alcoholic solution in small, very white, mammellated crystal It dissolves in all proportions in water and in alcohol at the boiling heat, but col water dissolves only traces of it.

The characters of this salt differ somewhat according as it has been prepared wit lactic acid α extracted from muscular flesh (sarcolactic acid), or from lactic acid β produced by the fermentation of sugar.

The salt of the acid α, deposited from an aqueous solution, contains 2 at. water; tha of the acid β crystallised in the same way contains 5 at. $Ca''(C^3H^5O^3)^2.5H^2O$. Th lactate α retains its water of crystallisation at 100° longer than the salt β. Lastly, th salt α requires 12·4 pts. of water to dissolve it; whereas the salt β dissolves in 9·5 pt Pure lactate of calcium, dried at 100°, and containing $Ca''(C^3H^5O^3)^2$, loses water a 280°, and is converted into dicalcic dilactate, $C^6H^5Ca''O^5$ (DILACTIC ACID, p. 461) (Wurtz and Friedel.)

Acid lactate of calcium, $Ca''(C^3H^5O^3)^2.2C^3H^6O^3.3H^2O$, obtained by mixing a solutio of the neutral lactate with as much lactic acid as it already contains, forms crystallin masses resembling wavellite. It dissolves in absolute alcohol, gives off its water o crystallisation at 80°, and rapidly turns brown at a higher temperature.

Lactate of calcium and potassium.—Obtained by incompletely precipitating a solu tion of lactate of calcium with carbonate of potassium. It forms hard crystals solubl in water.

Lactate with chloride of calcium, $Ca''(C^3H^5O^3)^2.Ca''Cl^2.6H^2O$.—Obtained in prisms b mixing the solutions of the two salts, and concentrating the liquid considerably.

LACTATE OF CHROMIUM is an uncrystallisable salt.

LACTATE OF COBALT, $Co''(C^3H^5O^3)^2.6H^2O$.—Peach-blossom-coloured needles, nearl insoluble in cold water, moderately soluble in boiling water, insoluble in alcohol. It solution has a slight acid reaction.

LACTATE OF COPPER, $Ca''(C^3H^5O^3)^2.3H^2O$ and $2H^2O$, is obtained by precipitatin sulphate of copper with lactate of barium, or by boiling carbonate of copper with lacti acid. By the latter method a basic salt is also produced, from which the product mus be purified by recrystallisation or by addition of lactic acid.

Lactate of copper α (sarcolactate) crystallises in sky-blue nodules containing 3 at water, which it does not give up at 100° till after a considerable time; whereas β form larger crystals, of a green or very dark blue colour, and containing 2 at. water, whic they give off by simple desiccation over sulphuric acid. The salt α exposed to gradually increasing heat does not exhibit any change below 210°; but at that tem perature it takes fire and burns, leaving a residue of metallic copper. β heated in lik

Digitized by Google

manner decomposes at 140°, leaving a residue of cuprous oxide. Lastly, α dissolves in 1·95 pt. cold water, and in 1·24 pt. boiling water, and in a small proportion of alcohol; whereas β requires for solution 6 pts. of cold water, 23 pts. boiling water, 115 pts. cold alcohol, and 26 pts. boiling alcohol.

Lactates of Iron.—*Ferrous lactate*, $Fe''(C^3H^5O^3)^2.3H^2O$, may be prepared by decomposing the calcium-salt with ferrous sulphate, or by mixing lactate of ammonium with ferrous chloride in presence of alcohol; also by boiling dilute lactic acid with iron-filings. It forms small crystals having a slight greenish tint; their solution oxidises but slowly on exposure to the air. This salt is sometimes used medicinally in the treatment of chlorosis.

Ferric lactate is a brown amorphous mass, deliquescent, and very soluble in water.

Lactate of Lead.—By treating carbonate of lead with boiling lactic acid, a neutral liquid is obtained, which when evaporated deposits a mass of small pellicles, and acquires an acid reaction.

Lactate of Magnesium, $Mg''(C^3H^5O^3)^2.4H^2O$ and $3H^2O$.—Obtained by dissolving magnesia in lactic acid. Crystallises in prisms permanent in the air, soluble in water, insoluble in alcohol. The salt α (sarcolactate) contains 4 at. water; the salt β contains 3 at. The salt α is also much more soluble in water and alcohol than β.

Lactate of Manganese, $Mn''(C^3H^5O^3)^2.3H^2O$.—Large, brilliant, amethyst-coloured crystals, moderately soluble in cold water, very soluble in hot water; soluble also in alcohol.

Lactates of Mercury.—*Mercurous lactate*, $(Hg^2)''(C^3H^5O^3)^2.2H^2O$. Rose-coloured or crimson crystals, obtained by mixing the boiling solutions of lactate of sodium and mercurous nitrate.

Mercuric lactate.—The neutral salt is not known. A basic salt, $Hg''(C^3H^5O^3)^2.Hg''O$, is obtained by boiling mercuric oxide with dilute lactic acid till the liquid is saturated. The solution yields by evaporation a yellow salt, insoluble in water, and a colourless salt which is very soluble. The latter, which has the composition above given, crystallises in shining prisms which effloresce rapidly in the air, and are very sparingly soluble in alcohol.

Lactate of Nickel, $Ni''(C^3H^5O^3)^2.3H^2O$.—Apple-green needles, very soluble in cold water, more soluble in hot water, insoluble in alcohol. The solution has a slight acid reaction. According to Engelhardt, the salt α gives off the whole of its water at 100°, but β does not part with the third atom before 130°.

Lactate of Potassium.—Very soluble, and crystallises with difficulty.

Lactate of Silver. $AgC^3H^5O^3.H^2O$.—Obtained by boiling carbonate of silver with lactic acid. It forms silky needles grouped in nodules, neutral to test-paper, blackening quickly by exposure to light, very soluble in warm alcohol, nearly insoluble in cold alcohol. The aqueous solution, when boiled for some time, acquires a fine blue colour, and deposits brown flakes. It may be heated to 80° without decomposing, but blackens and gives off gas at 100°. The air-dried salt contains 2 at. water, which it gives off *in vacuo*.

Lactates of Sodium.—*Monosodic lactate*, $NaC^3H^5O^3$. An amorphous, deliquescent mass, very soluble in water and absolute alcohol; ether precipitates it from its alcoholic solution. Dried at 140°, it possesses the above composition. (Wislicenus.)

Disodic lactate.—Monosodic lactate heated to 130° is acted on by sodium, hydrogen being liberated and a sodium-salt formed, which, together with unaltered monosodic lactate, contains disodic lactate. The product thus obtained is a bright yellow, very hard and brittle mass. It deliquesces quickly in the air. When covered with water, it is decomposed, with very perceptible development of heat, into monosodic lactate and hydrate of sodium. The deliquesced salt absorbs carbonic anhydride from the air; so that when it has been long exposed, absolute alcohol dissolves out monosodic lactate, leaving a residue of carbonate of sodium. Disodic lactate appears to dissolve without alteration in perfectly anhydrous alcohol. With iodide of methyl, it yields iodide of sodium and methyl-lactate of sodium. (Wislicenus, Ann. Ch. Pharm. cxiv. 49.)

Lactate of Strontium, $Sr''(C^3H^5O^3)^2.3H^2O$.—Neutral and very soluble.

Lactate of Tin. *Stannous lactate.* $Sn''(C^3H^5O^3)^2.Sn''O$.—This basic salt is obtained by mixing an acid solution of stannous chloride with lactate of sodium. It is a white crystalline powder, insoluble in cold water, very soluble in hydrochloric acid; soluble also in acetic acid after prolonged ebullition.

Stannic chloride mixed with lactate of sodium does not yield crystals, or a precipitate even after concentration to a syrup.

Lactate of Uranium.—Uranic lactate, $(U^2O^2)''(C^3H^5O^3)^2$, is obtained in yellow crystalline crusts by evaporating a solution of uranic oxide in lactic acid.

Lactate of Zinc, $Zn''(C^3H^5O^3)^2.3H^2O$ and $2H^2O$.—Prepared by boiling carbonate of zinc with lactic acid. The salt α (sarcolactate) is deposited, as the solution cools, in very dilute needles, irregularly grouped; on touching the vessel, these groups separate,

Digitized by Google

and the whole of the liquid solidifies to a pulp. The salt β forms sometimes shining crusts, sometimes large needles irregularly grouped.

The salt α contains 1 at., the salt β $\frac{3}{2}$ at. water, which it gives off quickly at 100° whereas α requires heating for several hours to dehydrate it completely. β may be heated without alteration to 210°, whereas α begins to give off empyreumatic vapours between 100° and 150°.

The two salts also differ greatly in solubility. α dissolves in 2·88 pts. of boiling and 5·7 pts. of cold water; in 2·23 pts. of cold alcohol, and in about the same quantity with boiling heat. The salt β requires for solution 6 pts. of boiling water, 58 pts. of cold water, and is nearly insoluble in alcohol.

According to Liebig, the neutral salt prepared with lactic acid from sourcrout splits up, when its solution is mixed with alcohol, into a basic and an acid salt. Engelhard did not observe this decomposition of the zinc-salt prepared with lactic acid obtained by the fermentation of sugar.

Derivatives of Lactic acid.

Acetolactic acid. $C^5H^8O^4 = \begin{matrix} C^2H^3O \\ (C^3H^4O)'' \\ H \end{matrix}\Big\}O$. (Wislicenus, Ann. Ch. Pharm. cxxv. 60.)—Obtained from acetolactate of ethyl (*vid. inf.*) by heating it with water to 150° for two or three hours. It is a thick, syrupy liquid; very easily soluble in water and has an agreeable, purely acid taste, without any irritating after-taste. It is not volatile without decomposition, but is carried over to a considerable extent by water vapour; even then, however, it is partially decomposed into acetic and lactic acids. Under all circumstances, indeed, both the acid and its salts readily undergo decomposition into these two acids.

Acetolactate of barium, $Ba''(C^5H^7O^4)^2.4H^2O$.—Acetolactic acid dissolves carbonate of barium, with evolution of carbonic anhydride. The solution is warmed for a very short time with excess of the carbonate, in order to complete the neutralisation (longer heating would cause decomposition into lactate and carbonate); then filtered and evaporated to a syrup on the water-bath. This syrup becomes a tough mass on cooling, and dries up over sulphuric acid *in vacuo* to a brittle and pulverisable substance resembling gum. It then still retains 4 molecules of water, two of which are given off at 100°, the remainder only at 140°. Acetolactate of barium is very soluble in water, and dissolves also in absolute alcohol. Ether produces in the alcoholic solution a flocculent precipitate, which soon unites into a tough, sticky mass.

Acetolactate of copper.—Obtained as a blue-green, amorphous, gummy mass, by decomposing the barium-salt with sulphate of copper, and evaporating. It dissolves easily in water and alcohol, and becomes moist when exposed to the air.

Acetolactate of zinc, $Zn''(C^5H^7O^4)^2$.—A cold solution of acetolactate of barium is decomposed with an exactly equivalent quantity of sulphate of zinc, and the liquid is evaporated over sulphuric acid without the aid of heat. The gummy mass thus obtained contains imbedded crystals of lactate and acetate of zinc. To separate these, the acetolactate of zinc is dissolved out by a small quantity of absolute alcohol. By evaporating the solution *in vacuo*, the salt is left as a gummy mass, which, when thoroughly dried over sulphuric acid, is not decomposed at 110°. Its solutions, both aqueous and alcoholic, become quickly acid, owing to the extraordinary ease with which the salt decomposes into acetate and lactate of zinc, and acetic and lactic acids.

Acetolactate of ethyl, $C^7H^{12}O^4 = \begin{matrix} C^2H^3O \\ (C^3H^4O)'' \\ C^2H^5 \end{matrix}\Big\}O$.– Formed by the action of chloride of acetyl on monethylic lactate (p. 463). This reaction, which was first mentioned by Perkin (Zeitschr. Chem. Pharm. 1861, p. 166), has been further investigated by Wislicenus (*loc. cit.* p. 58).

Acetolactate of ethyl is a colourless, mobile liquid, of an agreeable, aromatic smell, recalling that of Calville-apples. It is neutral, and insoluble in water, but is gradually decomposed by it into alcohol and acetolactic acid (see above). It dissolves in alcohol and ether in all proportions, and is precipitated by water from its alcoholic solutions. Boiling point 177°, under 733 mm. pressure. Specific gravity, 1·0458 at 17°, water at the same temperature being taken as unity; vapour-density, found 5·70, calculated 5·54.

Benzolactic acid. $C^{10}H^{10}O^4$. (See vol. i. p. 561.)

Butyrolactic acid. $C^7H^{12}O^4 = \begin{matrix} C^4H^7O \\ (C^3H^4O)'' \\ H \end{matrix}\Big\}O$. (See vol. i. p. 697.—To the description there given of butyrolactate of ethyl, we add the following particulars.)

Digitized by Google

Boiling point, 208°. Vapour-density, found 6·73, calculated 6·51. Heated with caustic potash in a sealed tube, it is decomposed into alcohol, and lactate and butyrate of potassium. (Wurtz, Ann. Ch. Phys. [3] lix. 177.—This mode of decomposition is important, since, were Kolbe's view of the constitution of butyrolactic acid correct, it ought to yield propionate and butylactate (oxybutyrate) of potassium when decomposed by potash. (Compare Ann. Ch. Pharm. cxiii. 234, 235, also vol. ii. p. 701 of this work.)

Dilactic acid. *Ankydrous lactic acid* (Pelouze), *Acide lactidique* (Laurent). $C^6H^{10}O^5 = \left.\begin{matrix}(C^3H^4O)''\\(C^3H^4O)''\\H^2\end{matrix}\right\}O^2$. This substance remains as a pale-yellow, amorphous, easily fusible mass, when lactic acid is exposed for some time to a temperature between 130° and 200°. It is converted into lactic acid, slowly by ebullition with water, quickly by the action of aqueous alkalis. By dry distillation, it is converted into lactide (p. 464). With gaseous ammonia it yields the compound $C^6H^{14}N^2O^4$, commonly called lactamate of ammonium, but more correctly dilactylamate of ammonium (p. 453).

Dilactate of calcium, $C^6H^8CaO^5$.—Obtained by heating lactate of calcium, previously dried at 100°, to 280°. It is much less soluble in absolute alcohol than lactate of calcium. (Wurtz and Friedel.)

Dilactate of ethyl. Monethylic dilactate, $C^8H^{14}O^5 = \left.\begin{matrix}(C^3H^4O)^2\\C^2H^5.H\end{matrix}\right\}O^3$, is formed by the action of chloropropionate of ethyl on lactate of potassium:

$$\underset{\text{Chloropropionate of ethyl.}}{\left.\begin{matrix}(C^3H^4O)''\\C^2H^5\end{matrix}\right\}Cl\,O} + \underset{\text{Lactate of potassium.}}{\left.\begin{matrix}(C^3H^4O)''\\HK\end{matrix}\right\}O^2} = \underset{\text{Monethylic dilactate.}}{\left.\begin{matrix}(C^3H^4O)^2\\C^2H^5.H\end{matrix}\right\}O^3} + KCl$$

It is a colourless, oily liquid, of specific gravity 1·134 at 0°; boiling point about 235°. It is decomposed, when heated with water in sealed tubes, into alcohol and lactic acid. (Wurtz and Friedel, Ann. Ch. Phys. [3] lxiii. 112.)

Monosulphodilactic acid, $C^6H^{10}O^4S$. (Schacht, Ann. Ch. Pharm. cxxix. 4.)—This acid was obtained as the product of an operation conducted with a view to the preparation of sulpholactic acid (p. 462). Instead of neutralising the aqueous solution of the crude product containing sulpholactate of potassium (see p. 462) with hydrochloric acid, it was neutralised with dilute sulphuric acid, and a further quantity of sulphuric acid was then added, sufficient to decompose the sulpholactate only. Monosulphodilactic acid then separated at the surface of the concentrated saline solution, and was obtained pure by solution in ether and evaporation under the air-pump.

Monosulphodilactic acid is soluble in water, alcohol, and ether, but does not crystallise. It contains the elements of two molecules of sulpholactic acid *minus* one molecule of sulphydric acid:

$$2C^3H^6O^4S - H^2S = C^6H^{10}O^4S.$$

By oxidation with dilute nitric acid, it yields dilactylsulphurous acid, $C^6H^{10}SO^7$ (*Dipropionschwefelsäure*, Schacht), the barium-salt of which is a white amorphous powder containing $C^6H^8Ba''SO^7$.

Ethyl-lactic acid. See Lactic Ethers (p. 463).

Lactylsulphurous acid. *Sulphopropionic acid*, $C^3H^6SO^4$.—This acid is formed by the action of fuming sulphuric acid on cyanide of ethyl, or on propionamide, in the process for preparing disulpholactic acid (Buckton and Hofmann, Chem. Soc. Qu. J. ix. 251); also when sulpholactic acid is oxidised with dilute nitric acid. (Schacht.)

Lactylsulphite of Ammonium is exceedingly soluble in water, and uncrystallisable. Absolute alcohol throws it down as a thick treacly mass.

Lactylsulphite of Barium, $C^3H^4Ba''SO^4$, crystallises from a saturated boiling solution in fine silky crystals, arranged in spherical groups. It may be dried at 170° without decomposition.

Dilactylsulphurous Acid. See above.

Lactyl- and dilactylsulphurous acids may be regarded as containing the radicles of lactic and sulphurous acids, and may be represented by the following rational formulæ:

$$\left.\begin{matrix}(C^3H^4O)''\\(SO)''\\H^2\end{matrix}\right\}O^2 \qquad \left.\begin{matrix}(C^3H^4O)''\\(C^3H^4O)''\\(SO)''\\H^2\end{matrix}\right\}O^4$$

Lactylsulphurous acid. Dilactylsulphurous acid.

Methyl-lactic acid. See Lactic Ethers (p. 464).

Succino-lactic acids. The only known representatives of these substances are

diethylic succinolactate, $C^{11}H^{18}O^6$, and diethylic succinodilactate, $C^{14}H^{22}O^8$. *Diethylic succino lactate*, $\left.\begin{matrix}(C^2H^4O^2)''\\(C^3H^4O)''\\(C^2H^5)^2\end{matrix}\right\}O^2$, is an oily liquid, insoluble in water, boiling at 280° and of specific gravity 1·119 at 0°, formed by the action of chloropropionic ether on succinate of ethyl and potassium in presence of alcohol. It is decomposed, when heated with baryta-water, into alcohol and succinate and lactate of barium.

Diethylic succinodilactate, $\left.\begin{matrix}C^4H^4O^2\\(C^3H^4O)^2\\(C^2H^5)^2\end{matrix}\right\}O^4$, is a liquid boiling between 250° and 270°, produced by the action of chloropropionate of ethyl upon succinate of potassium (Wurtz and Friedel.)

Sulpholactic acid, $C^3H^6O^2S = \left.\begin{matrix}(C^3H^4O)''\\H^2\end{matrix}\right\}\begin{matrix}S\\O\end{matrix}$. (Schacht, Ann. Ch. Pharm cxxix. 1.)—The potassium-salt of this acid is formed when an intimate mixture of chloropropionate of potassium and sulphydrate of potassium is heated for four or five hours to a little above 100°:

$$\underset{\text{Chloropropionate of potassium.}}{C^3H^4KClO^2} + HKS = \underset{\text{Sulpholactate of potassium.}}{C^3H^5KO^2S} + KCl$$

To prepare the acid, the mixture of chloride, phosphate, and chloropropionate obtained by neutralising with carbonate of sodium the crude product of the distillation of lactate of calcium with pentachloride of phosphorus, is mixed with sulphydrate of potassium (1 molecule of the latter for each molecule of lactate used), and the solution is evaporated and the residue heated as above. The product of this operation is dissolved in water, saturated with hydrochloric acid, warmed to expel sulphydric acid, largely diluted, made slightly alkaline with ammonia, and precipitated with acetate of lead. The lead-precipitate is thoroughly washed with *cold* water, then decomposed with sulphydric acid, and the filtered liquid repeatedly evaporated to a syrup to remove the hydrochloric acid. The residue is dissolved in water and neutralised at the boiling heat with carbonate of barium, which causes a precipitate of phosphate of barium, while sulpholactate of barium remains in the solution. From this solution the acid is again thrown down as lead-salt; the precipitate is decomposed by sulphydric acid; and the resulting solution of the free acid is concentrated by evaporation on the water-bath.

Sulpholactic acid crystallises in broad needles, grouped together in bundles or brushes; it melts without decomposition below 100°, and solidifies in the crystalline form. It dissolves in water, alcohol, and ether, and may be boiled in dilute solution without decomposing. Nitric acid, not in excess, oxidises it to lactylsulphurous acid, $C^3H^6SO^5$ (*sulphopropionic acid*, Buckton and Hofmann). (*vid. sup.*)

Sulpholactate of barium, $C^6H^{10}Ba''O^4S^2$.—Crystallises in cauliflower-shaped masses; dissolves easily in water, insoluble in alcohol; it is not altered when dried at 100°.

Sulpholactate of lead.—Amorphous, and becomes brown on keeping.

Sulpholactate of potassium is obtained by double decomposition from sulpholactate of barium and sulphate of potassium. The solution evaporated *in vacuo* to a syrup deposits broad plates which are very deliquescent.

Sulpholactate of silver, $C^3H^5AgO^2S$.—A white, amorphous precipitate obtained by adding nitrate of silver to a solution of sulpholactate of barium. It is soluble in nitric acid, and decomposes below 100°.

Trilactic acid. The diethylic ether corresponding to this acid is known. (See Lactic Ethers.) H. W. and G. C. F.

LACTIC ANHYDRIDE. Dilactic acid (p. 461) was formerly called anhydrous lactic acid, or lactic anhydride. The true lactic anhydride is Lactide (p. 464).

LACTIC ETHERS. Owing to its peculiar constitution as a mono-basic diatomic acid, lactic acid is capable of forming three different ethers containing the same monatomic alcohol-radicle. Thus there are three lactates of ethyl, which may be represented by the following formulæ:

$\left.\begin{matrix}H\\(C^3H^4O)''\\H\end{matrix}\right\}O$ Lactic acid.

$\left.\begin{matrix}C^2H^5\\(C^3H^4O)''\\H\end{matrix}\right\}O$ Ethyl-lactic acid, $\left.\begin{matrix}H\\(C^3H^4O)''\\C^2H^5\end{matrix}\right\}O$ Monethylic lactate.

$\left.\begin{matrix}C^2H^5\\(C^3H^4O)''\\C^2H^5\end{matrix}\right\}O^2$ Diethylic lactate.
